FUTURE DIRECTIONS AND CONCLUSIONS 391

REFERENCES 393

Few child difficulties generate as much controversy and concern in our society as problems with attention and impulse control. Much of this discussion centers on the clinical syndrome of Attention-Deficit/Hyperactivity Disorder (ADHD; American Psychiatric Association, 1994). Dramatically rising rates of medication treatments for children, particularly stimulants (Rappley, Gardiner, Jetton, & Houang, 1995; Robison, Sclar, Skaer, & Galin, 1999; Safer & Zito, 1999), have drawn the attention of social critics and clinical scientists alike (Brown, 2003). Sociologists point

out that medicalization of behavior occurs when a problem falls under the purview of the medical profession; for example, American society has seen the medicalization of pregnancy and birth, drinking problems, and other processes and conditions (Barsky & Borus, 1995; Conrad, 1992). The medicalization of attentional problems and hyperactivity, as well as disruptive behavior more generally, has spurred controversy over the validity of ADHD as a psychiatric disorder (Searight & McClaren, 1998) and sparked concern that rising medication rates may indicate an important

shortage of other needed psychological or educational interventions for children (Safer & Krager, 1992) or that social control is being served rather than mental health (Menzies, 1997). The concerns and criticisms attending ADHD have become so vehement, and so misguided at many levels, that a group of clinical and developmental scientists recently issued a consensus statement asserting the validity of the clinical syndrome of ADHD (Barkley, 2002) and experts continue to restate the elements of support for its validity (Faraone, 2005).

Along with the running public controversy, research on ADHD has also witnessed advances in the past decade. Particularly notable has been the development of more detailed neuropsychological theories that attempt to integrate the various cognitive findings regarding children with ADHD (Barkley, 1997, 2006; Nigg, 2001, 2006; Sagvolden, Johansen, Aase, & Russell, 2005; Sergeant, Oosterlaan, & van der Meere, 1999). These models emphasize the regulatory functions involved in executive control, regulation of arousal, and related processes that we discuss in this chapter. At the same time, theories that integrate the role of socialization processes along with neuropsychology in the *development* of these problem behaviors have been in shorter supply (Campbell, 2002; Johnston & Mash, 2001; Olson, 2002).

In light of widespread interest in it, we devote considerable space in this chapter to the ADHD syndrome, its likely causal mechanisms, its heterogeneity and subtypes, the boundaries of its validity as a disease construct, and its place in a developmental psychopathology framework. Because so much ongoing controversy and recent theorizing concerns the status of within-child developmental mechanisms, we emphasize internal neural and psychological control systems and their development. We also highlight the often overlooked role of the child's interpersonal network, plus wider societal contextual factors, which have key roles to play in the development and display of self-regulatory functions. First, the attainment of self-regulation in the preschool years is inherently an interpersonal process influenced by both child temperament and parent responsivity (Greenberg, Kusche, & Speltz, 1991; Stoolmiller, 2001). Second, family processes may be a primary mediator for the expression, over time, of the genetic mechanisms reflected in the apparently high heritability of these behavior problems. Third, at a broader level, societal concerns over the inattentive and disruptive behaviors of children have attained salience largely through the advent of compulsory education in our relatively recent historical past. Indeed, school- and community-related pressures for earlier and earlier academic competence in

recent years may well be influencing the development of attention processes across all children, as well as rates of referral for these problems in society.

We highlight at the outset that genetic and other child-specific mechanisms that influence *individual differences* in the expression of given traits or conditions (e.g., ADHD) are not commensurate with societal factors that shape the *overall levels* of such traits or conditions (see Rutter & Silberg, 2002; Nigg, 2006). For instance, individual differences in height are generally highly heritable, but the secular trends over the past century regarding substantially increased stature in the population at large (in developed nations) are the result of dietary and other environmental factors. Thus, we cannot ignore the rapid changes in society and in socialization influences on children as contributory factors to children's attentional and regulatory processes in general. Indeed, needed data on recent secular influences on ADHD-related problems are in short supply. Overall, we consider the notions of attention, impulse control, and self-regulation from the viewpoint of both normal and disordered developmental processes, because only through such a systematic developmental psychopathology perspective can an integrative account of this controversial area be promoted.

Before addressing ADHD *per se*, we note that problems with inattention and impulsivity cut across a range of psychiatric and clinical conditions. With regard to inattention, for example, Mirsky and Duncan (2001) listed some 17 conditions associated with disordered attention, including Schizophrenia, Autism, Fetal Alcohol Syndrome, closed-head injury, and narcolepsy. To their illustrative list could be added other medical conditions plus anxiety disorders, depression, and Obsessive-Compulsive Disorder from the psychopathology domain. Crucially, however, the term "attention" connotes multiple functions; not all such functions are equally affected across these various conditions. Thus, behavioral problems that appear as "inattention" may or may not be related to dysfunction in attentional mechanisms defined more formally. A range of causal mechanisms within the child could, in fact, be related to inattentive and otherwise dysregulated *behavior*.

Likewise, impulse control is multiply defined (see Nigg, 2000) and appears in one form or another in a range of conditions, of which ADHD may be the most prominent but is hardly the sole exemplar. Antisocial behaviors (including conduct problems and psychopathy), eating disorders, personality disorders (notably Borderline Personality Disorder and Antisocial Personality Disorder), substance abuse disorders, tic disorders, Obsessive-Compulsive Disorder, and Bipolar Disorder are only some of the psychopathologies

readily associated with serious maldevelopment of impulse control (Coles, 1997). Further, an entire section of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* is devoted to “impulse control disorders,” including kleptomania, intermittent explosive disorder, pyromania, pathological gambling, and trichotillomania (see Hucker, 1997, for further discussion). Many of these are syndromes primarily observed in adulthood, and their relation to childhood impulsivity is largely unstudied; yet there clearly is no one-to-one correspondence between the topic of disorders of attention and impulse control and the clinical syndrome of ADHD. Finally, as all of this implies, many different mechanisms have been suggested as causal within children with ADHD, not to mention related impulsive behavioral difficulties (Barkley, 1997; Berger & Posner, 2000; Casey, Tottenham, & Fossella, 2002; Castellanos & Tannock, 2002; Douglas, 1972, 1999; Newman & Wallace, 1993; Nigg, 2001, 2006; Nigg, Swanson, & Hinshaw, 1997; Sagvolden et al., 2005; Satterfield & Dawson, 1971; Sergeant, Oosterlaan, & van der Meere, 1999; Zentall & Zentall, 1983). We address many of the still viable hypotheses for ADHD in our coverage of the most studied mechanisms herein, as we also note intriguing new directions in the field for which data are still emerging. The extent to which the mechanisms we discuss may pertain to the full range of other impulse-related disorders remains a topic for another day.

We begin with a brief historical account of the clinical syndrome of ADHD and a description of its key features. Next, we consider in some detail the formal constructs of attention and impulse control, providing definitions of each as well as evidence for developmental patterns related to their display throughout childhood. Space does not allow us to catalogue the particular attention or impulse disturbances associated with every potentially relevant condition suggested earlier. Instead, we outline the core components of the development of attention and impulse control, pointing out particular implications for ADHD and emphasizing progress in the past 10 years, since the first edition of this volume. Developmental changes are notable throughout the life span, including young adulthood (Nigg, Stavro, et al., 2005) and old age (Hasher & Zacks, 1988; Zacks & Hasher, 1994), and we highlight very briefly the burgeoning research literature on ADHD in adults. Then, in keeping with the developmental psychopathology perspective of multiple levels of analysis (see Cicchetti & Dawson, 2002), we outline a multilevel, developmental perspective on ADHD and its variants during childhood, adolescence, and early adulthood. Our overall goal is to point out major pathways related to ADHD in an attempt to move the field toward a

more developmentally informed understanding of psychopathologies of attention and impulse control. We close with a comment on multiple developmental pathways and our view of key issues for the field in the coming decade.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER: HISTORICAL VIEWS AND RECENT NOSOLOGICAL ISSUES

The changes in conceptual definition of and treatment rates for ADHD over the years are one contributor to controversy about its status and meaning. It therefore is important to briefly review key historical changes in its conception and in rates of treatment. For additional historical review, see Barkley (2006).

Brief History

Well before current conceptual models began to be developed, educators and clinicians began to notice clinical-level manifestations of inattention, impulsivity, and dysregulated behavior in school-age children. Still (1902) presented a clinical description of so-called moral deficits in children, referring to problems of attention and deportment that were not clearly associated with mental subnormality. Thus, compulsory education was apparently leaving in its wake a subset of children who had salient difficulties in behavioral and emotional regulation or in the basics of reading and writing (with the latter eventually termed *learning disabilities*).

Following the worldwide influenza epidemic during and after World War I, some children developed encephalitis, and it was noted that many survivors of this infection developed significant problems in attentional deployment, regulation of impulses, and general behavioral control. Though a notable example of fallacious reasoning from consequent to presumed cause, this set of symptoms—whether or not triggered by encephalitis—became known as a “minimal brain damage” syndrome, a term later softened to “minimal brain dysfunction,” or MBD (e.g., Strauss & Lehtinen, 1947). By the 1960s, the boundaries of MBD had been stretched to include scores of symptoms, spanning nearly all of child psychopathology and learning problems (Clements & Peters, 1962; Wender, 1971). This historical category of pathology thus suffered from two key shortcomings: a vastly overinclusive list of constituent symptoms and a presumed (though unproven) neural etiology.

Others were calling for narrower and more descriptive appellations. Laufer and Denhoff (1957) described a “hyperkinetic disorder of childhood,” focusing more specifi-

cally on dysregulated motor behavior. The second edition of the *DSM* (American Psychiatric Association, 1968) adopted this narrower conception and nomenclature. An empirical tradition was also expanding, in which adult informant ratings of child behavior problems were subjected to factor analyses in an attempt to discern identifiable, empirically supported syndromes of psychopathology (e.g., Quay, 1972). Factors labeled “hyperactivity” and “immaturity” began to appear in such dimensionalized accounts of child problem behavior.

Based largely on the research of Douglas and colleagues (e.g., Douglas, 1972), in the 1970s and 1980s researchers in North America began to reconceptualize the core deficit of children considered “hyperkinetic” as related to dysregulated attention and impulse control rather than motor overactivity per se. By the time of *DSM-III* (American Psychiatric Association, 1980), the condition had been renamed “attention deficit disorder,” which was posited to consist of a subtype without hyperactivity and a second subtype with hyperactivity. The empirical tradition continued, with efforts to develop empirically based taxonomies of children that included dimensions related to hyperactivity and inattention (Achenbach, 1991; Achenbach & Edelbrock, 1978, 1983). By this time, research on children with clinically significant attentional and impulse control problems had begun to proliferate at an exponential rate. Further, stimulant medication treatments, which had originated decades earlier with the pioneering work of Bradley (1937), were generating controversy (Sroufe & Stewart, 1973), a theme that was to continue into the 1980s, 1990s, and beyond (Jacobvitz, Sroufe, Stewart, & Leffert, 1990; Safer & Krager, 1992).

Renamed Attention-Deficit/Hyperactivity Disorder, or ADHD, in *DSM-III-R* and *DSM-IV* (American Psychiatric Association, 1987, 1994, 2000), the condition’s core subtypes were expanded in the fourth edition to three: a Predominantly Inattentive type (similar to the *DSM-III* notion of attention deficit disorder without hyperactivity), a Predominantly Hyperactive-Impulsive type (unprecedented in previous nomenclatures), and a Combined type in which both symptom clusters were clinically salient.

By the 1990s, research on ADHD constituted a growth industry (e.g., Quay & Hogan, 1999). Legislative changes in the early 1990s yielded the inclusion of ADHD as a potential trigger for special education services in public schools, a factor that undoubtedly increased its salience to many families and clinicians. Prescription rates for stimulants, as for other psychotropic medications used with youth, had doubled in the United States in the 1980s, with even more rapid rises in the 1990s (Safer & Zito, 1999;

Zito et al., 2003). Meanwhile, major clinical trials had evidenced the efficacy of stimulant pharmacologic treatment for ADHD, if implemented carefully and with thorough monitoring, with combined medication-behavioral treatments yielding the highest likelihood of clinically meaningful improvement (Conners et al., 2001; MTA Cooperative Group, 1999). Finally, prospective longitudinal investigations were showing that ADHD was a condition likely to persist into adolescence in a majority of cases and to continue to yield impairment into adulthood in a substantial percentage (Mannuzza & Klein, 2000). Those findings led to the blossoming of research on ADHD in adults and the gradual recognition of the unique developmental issues facing the field in establishing validity of the construct in that age range, reflecting recognition of a research and clinical domain that was quietly under way for 3 decades (Wood, Reimherr, Wender, & Johnson, 1976). Thus, today ADHD is no longer considered a condition restricted to childhood or even adolescence, as growing interest in adults with this disorder characterizes today’s clinical and research landscape.

Features and Issues

Table 9.1 lists the *DSM-IV* features of ADHD, the *International Classification of Diseases (ICD-10*; World Health Organization, 1972) symptoms of hyperkinetic disorder (HKD), and the current diagnostic algorithms in use to define this disorder. Although the symptom lists are similar, several distinctions can be seen between ADHD and HKD, reflecting ongoing differences in how this syndrome is defined in Europe and the United States. It is unclear to what extent major findings apply equally to HKD and the more broadly defined ADHD. We nonetheless use the term ADHD to cover both constructs and to cover studies in which ADHD was defined by extreme rating scale scores. Like most psychiatric/developmental disorders of childhood onset, ADHD shows a male preponderance, on the order of 3:1 in community samples (Wolraich, Hannah, Baumgaertel, & Feurer, 1998). Among many possible salient issues and questions, we highlight several core issues for this construct.

First, note from Table 9.1 that the diagnosis of ADHD requires not only above-threshold numbers of symptoms but also (1) the early onset of these symptoms, (2) their developmental extremity (a key point, given that problems of inattention and impulsivity are ubiquitous in young children), (3) their cross-situational display (i.e., at home, at school, and often in the peer group or work setting), and (4) the requirement that they yield functional impairment.

TABLE 9.1 Diagnostic Criteria for ADHD in *DSM-IV* and Hyperkinetic Disorder in *ICD-10*

<ol style="list-style-type: none"> 1. Fails to give close attention to details or makes careless mistakes in schoolwork, work, or other daily activities. 2. Has difficulty sustaining attention on tasks or play activities. 3. Does not seem to listen when spoken to directly. 4. Does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions). 5. Has difficulty organizing tasks and activities (<i>ICD-10</i>: “Is often impaired in organizing tasks”). 6. Avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort such as schoolwork or homework. 7. Loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools). 8. Is easily distracted by extraneous stimuli (<i>ICD-10</i>: “by external stimuli”). 9. Is forgetful in daily activities (<i>ICD-10</i>: “in the course of daily activities”). 10. Fidgets with hands or feet or squirms in seat (<i>ICD-10</i>: “on seat”). 11. Leaves seat in classroom or in other situations in which remaining seated is expected. 12. Runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness). 13. Has difficulty playing or engaging in leisure activities quietly (<i>ICD-10</i>: “Is often unduly noisy in playing or has difficulty in engaging quietly in leisure activities”). 14. Is “on the go” or often acts as if “driven by a motor” (<i>ICD-10</i>: “Exhibits a persistent pattern of excessive motor activity that is not substantially modified by social context or demands”). 15. Talks excessively (<i>ICD-10</i>: “without appropriate response to social constraints”). 16. Blurts out answers before the questions have been completed. 17. Has difficulty awaiting turn (<i>ICD-10</i>: “Fails to wait in lines or await turns in games or group situations”). 	<ol style="list-style-type: none"> 18. Interrupts or intrudes on others (e.g., butts into conversations or games). <p><i>Each behavior must occur “often” and must persist for at least 6 months to a degree that is maladaptive and inconsistent with developmental level.</i></p> <p>Subtypes</p> <p><i>DSM-IV</i> ADHD-C: 6 items from 1–9, plus 6 items from 10–18.</p> <p><i>DSM-IV</i> ADHD-PI: 6 items from 1–9.</p> <p><i>DSM-IV</i> ADHD-HI: 6 items from 10–18.</p> <p><i>ICD-10</i> Hyperkinetic Disorder: 6 items from 1–9, plus 3 items from 10–14, plus 1 item from 16–18.</p> <p><i>DSM-IV</i> specifies a diagnosis of “in partial remission” for adolescents or adults who formerly met full criteria but now have some symptoms without meeting full criteria.</p> <p>Comorbidity</p> <p><i>ICD-10</i>: Specifies “do not diagnose” if child meets criteria for Pervasive Developmental Disorder, manic episode, depressive episode, or anxiety disorders. Specifies that Conduct Disorder excludes HDK diagnosis.</p> <p><i>DSM-IV</i>: Specifies that symptoms should not be “better accounted for” by another mental disorder.</p> <p>Additional Criteria</p> <p>Onset: Symptoms that caused impairment had to be present before 7 years of age (<i>DSM-IV</i>), or “onset of the disorder” is no later than age 7 (<i>ICD-10</i>).</p> <p>Pervasiveness: Impairment must be present (<i>DSM-IV</i>) or criteria must be met (<i>ICD-10</i>) in two or more settings.</p> <p>Impairment: There must be clear evidence of clinically significant impairment in functioning (<i>DSM-IV</i>); impairment or distress (<i>ICD-10</i>).</p>

Source: Adapted from *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, by the American Psychiatric Association, 1994, Washington, DC: Author; and *The ICD-10 Classification of Mental and Behavioral Disorders: Clinical Descriptions and Diagnostic Guidelines*, by the World Health Organization, 1992, Geneva, Switzerland: Author.

These guidelines have strong empirical support. Failure to assess impairment, in particular, likely inflates prevalence estimates (Gordon et al., 2005) and inclusion of parent and teacher standardized ratings greatly enhances assessment validity (Pelham, Fabiano, & Massetti, 2005). Thus, accurate assessment requires, at a minimum, the taking of a careful history; reports from multiple adult informants with well-normed rating instruments; differential diagnostic procedures to distinguish ADHD from either normal developmental variation or a host of medical and psychiatric conditions that feature inattention and impulse control problems in their presentation; and, when possible, direct observation of the child in family and school contexts. Careful consideration of functional adjustment in multiple domains can further assist with treatment tailoring (Pelham et al., 2005). Indeed, much of the controversy surrounding ADHD relates to the unfortunate tendency—

fueled by inadequate funding of thorough evaluations—for clinicians to make a diagnosis based on extremely short periods of assessment utilizing nonstandard and subjective diagnostic procedures.

Second, is the clinical syndrome of ADHD a distinct category or taxon, or do the constituent symptoms conform more closely to a dimension of behavioral dysregulation? A formal taxometric analysis (Waller & Meehl, 1998) is lacking. In the meantime, most relevant research converges on the conclusion that ADHD is better viewed as a dimension than as a distinct category, even at the level of underlying genetic risk for the condition (Levy, Hay, McStephen, Wood, & Waldman, 1997; Levy, McStephen, & Hay, 2001; Willcutt, Pennington, & DeFries, 2000). Yet, as with other dimensional entities (e.g., hypertension, depression), this likelihood does not negate the clinical importance of identifying and treating ADHD as a clinical syndrome. Indeed,

the *DSM-IV* conception of ADHD identifies children with functional impairments in key areas of developmental relevance, such as peer rejection, academic underachievement, family dysfunction, lowered independence, and high risk for accidental injury (Hinshaw, 2002b). Such impairments are evident as early as the preschool years (Lahey et al., 1998). ADHD is also a risk factor for problems later in development: It fuels an early start of aggressive behavior in some cases, which is predictive of delinquency, and it is also associated with school dropout, problems in social competence, and underemployment by adolescence and adulthood (Johnston, 2002).

Third, what is the status of the current subtyping scheme for ADHD as represented in *DSM-IV*? At a *dimensional* level, numerous investigations have confirmed a two-factor structure underlying the constituent symptomatology, corresponding to inattentive-disorganized and hyperactive-impulsive symptom domains. Both areas can be reliably measured by parent and teacher rating scale instruments. They show divergent validity, with inattentive behaviors uniquely associated with academic problems and hyperactive/impulsive behaviors aggregating with disruptive tendencies in school and home settings (Lahey & Willcutt, 2002). Thus, the underlying dimensions of ADHD show considerable psychometric viability. On the other hand, despite contentions that the purely Inattentive type of ADHD is qualitatively distinct from the Combined and Hyperactive-Impulsive (HI) variants (Milich, Balentine, & Lynam, 2001), empirical data are far from conclusive in this regard (Hinshaw, 2001; Lahey, 2001). In fact, with respect to neuropsychological processes, the Inattentive and Combined types often reveal more similarities than differences (Chhabildas, Pennington, & Willcutt, 2001; Hinshaw, Carte, Sami, Treuting, & Zupan, 2002; Nigg, Blaskey, Huang-Pollock, & Rappley, 2002), although they may be distinguishable on key measures such as response suppression (Nigg, Blaskey, Huang-Pollock, & Rappley, 2002). Family studies asking whether ADHD subtypes “breed true” have been mixed; a recent meta-analysis suggests that reliable familial separation of the Combined and Inattentive types exists, but only to a small extent, perhaps due to heterogeneity in both groups (Stawicki, Nigg, & von Eye, in press). Meantime, innovative behavioral genetic analyses suggest that the HI type is, unlike the others, not heritable (Willcutt et al., 2000); its validity in school-age children may be in question. Last but not least, the stability of subtype classification over time remains unclear (Lahey et al., in press). Alternative subtype schemes may enable clearer genetic effects (Neu-

man et al., 1999). In all, the subtyping scheme for ADHD mandates further scrutiny.

Fourth, although ADHD does not disappear with puberty, as was formerly contended, the cessation of formal schooling and the development of coping mechanisms may assist many adults in making important adaptations to this condition. Indeed, long-term outcomes for children with ADHD are highly variable (Barkley, 2006; Mannuzza & Klein, 2000). Along developmental lines, we note that the hyperactive-impulsive symptom cluster is likely to be particularly salient during the preschool and grade school years but fades in frequency and intensity by adolescence. On the other hand, the inattentive symptom cluster, which becomes recognizable with the advent of formal schooling, is more stable throughout adolescence (Hart, Lahey, Loeber, Applegate, & Frick, 1995). Thus, the HI subtype of ADHD, evident during preschool years, may give way to the Combined type once formal schooling begins (Lahey et al., in press). Furthermore, symptoms of overtly hyperactive behavior may give way to subtler forms of impulsivity once childhood is left behind, so that the inattentive problems may become most salient for late adolescents and adults. Finally, heterotypic continuity is not well addressed in the diagnostic system: Behaviors that describe ADHD in children may not be the best descriptors of the problems that impair affected individuals as adolescents or adults. Formal criteria to reflect any such developmental changes are completely lacking in the *DSM-IV* and *ICD-10*. However, research efforts are under way to fill this gap (Achenbach, 1991; Conners, 1997).

Although space permits only a limited comment on the rich topic of ADHD in adulthood, we highlight that when ADHD is identified in adults, the two largest and most definitive studies to date demonstrate similar magnitudes of neuropsychological impairment in executive functioning as that seen in children with the condition (Murphy, Barkley, & Bush, 2001; Nigg, Stavro, et al., 2005). These data strongly suggest that neuropsychological difficulties are not simply part of a developmental delay, but are a persistent feature of the syndrome when it persists into adulthood. Moreover, new impairments unique to adults must be considered, notably the potential for driving accidents and driving-related problems and problems in maintaining steady employment and intimate relationships (Barkley, 2004). A final complexity unique to the condition in adults concerns the potential for misdiagnosis in relation to Axis II psychopathology, or, in other words, the possibility that ADHD may develop into an enduring maladaptive personality style or trait by adulthood. This question has been

scarcely studied. Initial data from the Michigan State study indicate that ADHD is associated with elevated risk of several personality disorders in both the impulsive cluster (Borderline, Histrionic, and Antisocial Personality Disorders) and the anxious cluster (Avoidant Personality Disorder), but that these co-occurring disorders do not account for either the impairments experienced by these adults or for their neuropsychological deficits (T. Miller, Nigg, & Stavro, 2005). We address additional developmental trends again subsequently.

Fifth, ADHD is highly likely to exist in concert with other, presumably independent psychiatric conditions. Thus, substantial rates of overlap exist with disruptive disorders (Oppositional Defiant Disorder and Conduct Disorder), anxiety disorders, and learning disorders (Angold, Costello, & Erkanli, 1999). Such comorbidity is a huge and fascinating topic in its own right (see Caron & Rutter, 1991; Jensen, Martin, & Cantwell, 1997). The presence of ADHD in conjunction with additional childhood conditions presents major issues with respect to its heterogeneity. Indeed, some have contended that when ADHD co-occurs with clinically significant aggression or with major internalizing (anxious, depressed) features, it constitutes a substantially different condition than when it exists alone (e.g., Jensen et al., 2001). Indeed, unlike the *DSM*, the *ICD-10* diagnostic criteria explicitly recognize such comorbid forms as separable diagnostic categories (e.g., hyperkinetic conduct disturbance; see Table 9.1).

Moreover, virtually all neuropsychological findings pertaining to ADHD (e.g., executive function, arousal, reward abnormalities) can also be observed to at least some degree in children with other conditions, including, notably, other externalizing disorders such as Conduct Disorder, illustrating the nonspecificity of most such effects (Sergeant, Geurts, & Oosterlaan, 2002). Only a very few studies have controlled for possible ADHD symptoms in children with Oppositional Defiant or Conduct Disorder, or controlled for oppositional or conduct symptoms in children with ADHD, in order to begin to tease this out. Those few studies generally suggest that neuropsychological weaknesses hold for ADHD even when other symptoms are covaried (Chhabildas et al., 2001; Hinshaw et al., 2002; Klorman et al., 1999; Nigg, 1999; Nigg, Hinshaw, Carte, & Treuting, 1998). Yet the converse—that is, neuropsychological weaknesses in Conduct Disorder or aggression when ADHD is covaried—has also been reported (Seguin, Boulerice, Harden, Tremblay, & Pihl, 1999; Seguin, Nagin, Assaad, & Tremblay, 2004). Whereas specificity is not a necessary requirement for causality in multifactorial disorders such as ADHD (Garber & Hollon, 1991) and although effect sizes

on key neuropsychological probes are typically larger in relation to ADHD than other conditions (Oosterlaan, Logan, & Sergeant, 1998; Pennington & Ozonoff, 1996), this state of affairs exemplifies that the current nosology is descriptive and not etiologically anchored. We do not report on this general nonspecificity in each subsequent section, but we note here its overarching importance as a context for theorizing.

Sixth, as for a brief highlighting of risk and etiologic factors, a spate of behavioral genetic investigations in the past 15 years has provided evidence that the heritability of ADHD symptoms as well as of the syndrome is moderate to strong (see Levy, McStephen, & Hay, 2001; Swanson & Castellanos, 2002). We highlight, in passing, that the high end of some of these heritability estimates (.8 and above) emanate from investigations in which parents, who typically provide information on the twins' zygosity, are also the source of the behavioral ratings of the children. These estimates are likely inflated by rater contrast effects (Eaves et al., 2000). When teacher data constitute the dependent variable, estimates of heritability are lower, albeit still substantial. Molecular genetic evidence is still being accumulated; many candidate genes with replicated effects in ADHD are related to dopamine neurotransmission (Faraone et al., 2005; Kirley et al., 2002), although these individual genes contribute only a small fraction of the genetic variance, suggesting that many genes are likely involved. Genes affecting other neural systems, notably noradrenergic receptors, are undoubtedly implicated as well (Biederman & Spencer, 1999; Comings et al., 2000; Faraone et al., 2005; Park et al., 2005). Other biological risk factors include, in some cases, prenatal and perinatal problems, such as low birthweight and maternal tobacco or alcohol use during pregnancy (e.g., Botting, Powls, Cooke, & Marlow, 1997; Taylor, 1999), postnatal lead exposure (Canfield, Gendle, & Cory-Slechta, 2004), and potentially other widespread environmental toxins and contaminants (Koger, Schettler, & Weiss, 2005; Nigg, 2006; Rice, 2000). Several neuroimaging studies now confirm that groups of children with ADHD have smaller neural structures in key regions of the prefrontal cortex, basal ganglia, and cerebellum (Swanson & Castellanos, 2002). These dysplasias appear early in development, prior to treatment, and are apparently nonprogressive (Castellanos et al., 2002), although longitudinal studies remain vanishingly rare.

Only a handful of investigations implicate faulty parental discipline styles as causal risk factors for ADHD (E. A. Carlson, Jacobvitz, & Sroufe, 1995). In fact, the typical assumption is that disrupted parenting and discordant parent-child interactions result from, rather than cause,

temperamentally mediated child noncompliance and impulsivity. We point out, however, that problematic parent-child relationships may well be significant maintaining and exacerbating factors related to ADHD, yielding reciprocal, transactional chains of influence in conjunction with the child's core symptomatology (Hinshaw, 1999; Johnston & Mash, 2001). To foreshadow one of our themes, developmental paths to clinically significant inattention and impulse control problems are highly likely to involve both equifinality, meaning that several causal routes are contributory to ADHD, and multifinality, whereby early risks for ADHD may yield substantially divergent outcomes contingent on socialization and contextual processes (Cicchetti & Rogosch, 1996; Hinshaw, 1999).

With all that said, perhaps the most pressing issue at present concerns resolution of *within-child* causal mechanisms that contribute to ADHD's multifactorial expression as a behavioral syndrome. Thus, from here on, we are concerned less with the syndromal definition of ADHD and more with within-child mechanisms that may be related to development of behavior problems related to inattention and impulse dyscontrol (including their expression as the clinical syndrome of ADHD). Given the evidence for the heterogeneity of ADHD at multiple levels, such as symptomatology and subtypes, comorbidity, etiologic and risk factors, and developmental course, we therefore now explicitly take up the topic of more formally defined attention and regulation mechanisms as a means of clarifying and specifying the origins of such heterogeneity. Appreciation of attentional and regulatory processes at specific levels of understanding may help in the quest for understanding the highly variable behavioral manifestations of disorders of "attention" such as ADHD. In fact, because they are candidates for specifying within-child causal mechanisms in ADHD, understanding these specific attention and impulse control mechanisms may be essential to putting to rest debates about whether ADHD is a valid disorder (Wakefield, 1992). Thus, we move now to an analysis of psychological, behavioral, and neural systems underlying the development of these problems.

ATTENTION AND IMPULSE CONTROL IN DEVELOPMENT: OVERVIEW OF PSYCHOLOGICAL, BEHAVIORAL, AND NEURAL SYSTEMS

The development of attention and of impulse control are closely related. Both can be influenced, for example, by sensory reflex response, although we emphasize those effects primarily in our discussion of attention. Another,

more salient arena of their conceptual integration is in affect and motivation: Both attention and impulse can be redirected by strong anxiety due to a potential threat or strong excitement due to potential reward. This reactive regulation of attention and impulse control can be observed as early as late infancy (Rothbart & Ahadi, 1994). Another obvious area of their intersection is in the widely discussed domain of executive functions, which develop somewhat later than reactive effects and the precursors of which begin to influence children's attention and behavior by the toddler years in the form of effortful redirection of attention (Rothbart & Bates, 1998). Likewise, both attention and impulse control are moderated by the child's *energetic state*, that is, the level of arousal or tendency to arousability. Thus, from early infancy on, developing attention mechanisms assist with self-regulation and impulse control (including emotion regulation, behavioral control, and cognitive control). Likewise, the neural systems that support certain attentional skills are closely related to those that support control of motor responses, or impulses (Calkins & Fox, 2002). Finally, the development of these neural and behavioral systems is in constant interplay with the child's interpersonal world (e.g., parenting attunement, verbalization of affect; Greenberg et al., 1991).

Despite their close connections, however, for expository purposes the elements of attention and impulse control can be understood as partially distinct. They do not always operate in perfect tandem; they may develop at different rates and they can be measured in distinct ways. We therefore adopt a taxonomic approach to the various functional domains at hand. Skipping sensory or motor reflexive responses for now, and saving discussion of arousal until our coverage of attention proper, our plan is next to provide a description of reactive (motivated) processes and an introduction to strategic control via the integrative, widely discussed, and much critiqued concept of *executive functioning*. With that background, we then proceed to a developmental conceptual framework for attention functions and then impulse control functions. We subsequently highlight the main findings relevant to ADHD in both the attention and impulse control domains.

Reactive or Motivational Processes in Attention and Impulse Control

In contradistinction to the deliberate or strategic allocation of attention (or control of impulse), reactive processes involve emotional and affective states. Thus, when she notices something anxiety-provoking, a child may direct her attention to the concerning event or person (Gray, 1982;

Gray & McNaughton, 1996; Kagan, Reznick, & Snidman, 1987). Likewise, anxiety or excitement can narrow the focus of attention (Derryberry & Tucker, 1994). Thus, even though attention is usually viewed as a cognitive process, it is just as often (if not always, to some degree) motivated by incentive concerns. These same incentives can also influence impulse control, leading either to a very strong impulse to action (e.g., excitement from an imminent reward) or to inhibiting some or all behavior (e.g., confrontation with an anxiety-provoking or unfamiliar situation). Such motivated responses are often relatively spontaneous, and they are relatively more automatic than the more deliberate responding characteristic of effortful control.

Neurally, these reactive or affectively guided responses and shifts of attention and impulse are influenced by limbic networks, including the hippocampal formation and the amygdaloid complex (Gray, 1982; Kagan & Snidman, 2004). We already noted that these reactive processes come online and influence attention and impulse control earlier in development than do effortful types of processes (Rothbart & Ahadi, 1994). In considering both attention and impulse control, then, we consider how the role of affective and motivated responding can contribute to understanding ADHD. However, reactive processes interact with effortful processes in guiding moment-to-moment attention and impulse control by the early preschool years onward.

Executive Functions and Cognitive Control in Both Attention and Impulse Control

Another intersection of attention and impulse control is that both are related to the important but ill-defined domain of *executive function* (EF). It is widely agreed both that executive functioning is central to understanding attention and impulse control and that it is an underspecified construct (Pennington & Ozonoff, 1996; Zelazo, Muller, Frye, & Marcovitch, 2003). In a neuropsychological framework, EF refers to strategic or relatively deliberate regulation of response to context and maintenance of behavior in relation to goals (Pennington & Ozonoff, 1996). In the cognitive neuroscience field, this term is being supplanted by the term “cognitive control,” which refers to such operations as control of interfering information and suppression of reflexive responding (Casey et al., 2002). We take note of insights from that work but retain the older term EF here due to its continued widespread use in the clinical and developmental literatures. Several initial explanatory points about EF are in order.

First, although a common factor may underlie many executive tasks, EF cannot be readily analyzed only at the

global level. Instead, it generally must be viewed through the lens of component operations, which themselves are insufficiently specified. These components presumably work together to create the potential for strategic—or what we experience as deliberate—control of attention and impulse. Yet, agreement is not at hand as to the correct subdividing of the multidimensional EF domain (Barkley, 1997; Lyon & Krasnegor, 1996; Monsell & Driver, 1998). That literature is beyond the scope of our discussion, but we emphasize that subdividing is helpful in specifying mechanisms of ADHD. Numerous studies indicate that EF measures tap partially dissociable functions (Friedman & Miyake, 2004; Mirsky & Duncan, 2001; Miyake, Friedman, Emerson, Witzki, & Howerter, 2000). For example, one dimension involves working memory, selective attention, control of interfering information, and set shifting (Dempster, 1993; Engle, 2002; Mirsky & Duncan, 2001). We discuss those abilities in our coverage of attention later. Another dimension entails the ability to inhibit competing information and/or suppress a response, perhaps aided by a primary goal set (Friedman & Miyake, 2004; Logan & Cowan, 1984; Nigg, 2000; Pennington, 1997), although whether the actual operative mechanism is in various measurement paradigms is an inhibitory one remains unclear for many tasks. Such deliberate *response suppression* figures prominently in our subsequent coverage of impulse control. Numerous other functions have been attributed to the executive domain, underscoring the various conceptions of this construct. For example, in his influential theory of ADHD, Barkley (1997, 2006) offers very broad constructs that entail nearly all of self-regulation, including response inhibition, working memory, regulation of arousal-affect-motivation, internalization of speech, and reconstitution. Pennington and Ozonoff (1996) suggest set shifting, working memory, planning, behavioral inhibition, and interference control as among the key functions. Fuster (1997), as we noted, emphasizes temporal organization of behavior. That perspective has heavily influenced psychopathology research, as illustrated by theorists' recent emphasis on temporal information processing in ADHD (Barkley, 1997; Castellanos & Tannock, 2002).

Second, tractable models of EF are emerging (Lyon & Krasnegor, 1996; Posner & DiGirolamo, 1998), with a developmental focus (Diamond, Prevor, Callender, & Druin, 1997; Zelazo et al., 2003) and anchored in the neural sciences, where the term *cognitive control* (Monsell & Driver, 1998) has gained ascendancy as noted. These neural models all emphasize anterior networks in the brain and associated cortical-subcortical neural circuits (Casey et al., 2002). For example, with regard to attention, Posner and

DiGirolamo describe a control module that involves the anterior cingulate (a region of the frontal cortex) during active suppression of a competing response (e.g., the Stroop task) but not during automatic or rote responding (also see Norman & Shallice, 1986). Parenthetically, it is unclear whether the anterior cingulate is involved in monitoring response consequences (whether the consequence was expected or unexpected; Ito, Stuphorn, Brown, & Schall, 2003) or detecting response conflict (Botvinick, Braver, Barch, Carter, & Cohen, 2001). Either way, it anchors a network relevant to the development of attention and thus potentially to ADHD.

With regard to impulse control, similar frontal-subcortical neural circuits are implicated in suppressing responses (Casey et al., 2002). For example, suppressing inappropriate motor response during complex behavior appears to involve the dorsolateral prefrontal cortex, at least in young children (Diamond et al., 1997), as well as the orbitofrontal cortex (Aron, Fletcher, Bullmore, Sahakian, & Robbins, 2003; Posner & DiGirolamo, 1998) and the subcortical connections to each. Indeed, the subcortical and striatal structures to which these prefrontal regions are connected may be crucial in the actual suppression of a response (Kimberg & Farah, 1998) at least in certain contexts (Nigg & Casey, in press). A recent process conception of EF emphasizes deliberate problem-solving steps, such as representing and manipulating the problem in working memory (planning), carrying out an intended action rather than a competing action, and detecting mismatch to expected results or success (Zelazo et al., 2003). Those functions likewise have clear relevance to attention and impulse control.

Third, we stress that our division into attention and impulse control functions is heuristic, yet to some degree untenable. In moment-to-moment behavior, these functions are virtually inseparable. Likewise, the neural systems we describe are closely related. As a result, Posner and Rothbart (2000) argue that the anterior neural system associated with executive functions is involved in the strategic control of both attention and motor response. Psychometrically, recent data in adults also support the idea that certain functions, such as protecting attention from interference and suppressing a response conflict, are closely related (Friedman & Miyake, 2004), whereas other functions, such as set shifting, can be distinguished from these (Miyake et al., 2000).

Fourth, relevant to our developmental interest, these models all describe abilities that emerge and develop rapidly in the preschool period, continue to mature through middle childhood and adolescence, peak in early adult-

hood, and are among the first abilities to wane with the passing of middle age. This trajectory may be related to the late maturation of the frontal cortex: Neural development of these frontal networks (especially via synaptic pruning; Casey, Durston, & Fossella, 2001) appears to continue even into early adulthood (Benes, 2001), and it is generally believed that the last abilities to mature are the first to decay with late age-related decline in cognitive efficiency (Plude, Enns, & Brodeur, 1994). With regard to early development, strategic control of impulse is related in part to the *effortful control* construct in temperament theory (the ability to delay or interrupt task-inappropriate behavior; Rothbart & Bates, 1998). Therefore, early precursors of EF, in the form of effortful control, can be observed in the toddler years well before most cognitive EF probes can be employed or true complex behavioral sequencing is possible. Effortful control shows longitudinal stability, with high scores for this ability associated with development of adaptive behaviors (Kochanska, Murray, & Coy, 1997; Kochanska, Murray, & Harlan, 2000). Excessively *high* control is associated with internalizing problems. Important for our purposes, *low* levels of this potential precursor of later executive control are associated with externalizing behavior problems over the preschool years (Murray & Kochanska, 2002). In all, it is important to recognize that the EF capacities are expected to mature slowly in conjunction with the maturation of frontal cortical neural structures through adolescence and beyond. Their development in childhood is therefore a key area for understanding how psychopathologies of attention and impulse control emerge. Moreover, their relatively late maturation may illuminate ADHD's changing presentation in adolescence/adulthood.

Fifth, on the basis of the temperament literature, examining the development of these within-child functions enables us to consider the role of *scaffolding* by caregivers in the early rearing environment as well as the role of *stress* and *learning* in the development and maintenance of problems in attention and impulse control. Therefore, after we consider executive control of attention and impulses, we look more closely at socialization. In fact, a key theme of this chapter is that exclusively biological views of temperament and executive functions, without due consideration of social factors and of interactions and transactions between within-child factors and environmental influences, are destined to be inadequate to the task of understanding the development of problematic attention, impulse control, and self-regulation. Having given reactive and executive processes initial definition, we now proceed to a more extensive conceptual framework for attention and impulse control per se.

Attention: Conceptual Framework

Attention usually refers to the facilitated processing of one source of information over another, although broad usages of the term can include capacity pool (Engle, 2002) as well as response readiness, arousal, and regulation (Taylor, 1995) and other abilities (Mirsky & Duncan, 2001). With regard to mechanisms, as outlined by Yantis (1998), attentional selection can be based on spatial location (Erikson & Hoffman, 1972), object features (Triesman & Gelade, 1980; Wolf, 1998), and timing (Shapiro & Raymond, 1994), movement, or other object characteristics (Kahneman & Henik, 1981). Attentional selection is influenced by multiple component functions, including bottom-up stimulus-driven processes that are relatively automatic and relatively early developing, and top-down goal-driven processes that are strategic, relatively deliberate, related to the concept of executive control, and later developing. These two types of processes interact continuously, each placing constraints on the other (Schneider & Shiffrin, 1977). Researchers attempt to isolate these two influences in varying ways. At the same time, as noted earlier, often overlooked in the purely cognitive approaches to attention is the role of affective motivation in attentional allocation (Pennington, 2002).

The complexity of the cognitive component of attention alone has led to a massive literature. We cannot do justice to the many approaches available (Theuwes, Atchley, & Kramer, 1998; Triesman & Gelade, 1980; Yantis, 1998; see Monsell & Driver, 1998). Instead, we comment illustratively on key approaches that have influenced research on the psychopathology of attention in ADHD in recent years. The framework we adopt posits three basic functional distributed neural networks (Posner & Peterson, 1990), implementing in turn (1) reflexive and (2) strategic attention as well as (3) general alertness. In noting different models of attention, we reference them to these three basic networks. Table 9.2 schematizes the networks in relation to basic operations. As it indicates, within this general framework, we

can begin by thinking of visual *orienting* (facilitation of processing at specific locations in space) as well as object *selection* (filtering of information once a location is attended), both of which are supported by neural attention systems located in the posterior (relatively automatized operations) as well as anterior (relatively deliberate operations) anatomical regions of the brain.

Posterior Attention System

With regard to spatial orienting, we note that location holds a special place in the success of attention (at least visually) because in many respects, attention must be directed to a specific location for other processing to occur there (see Yantis, 1998, for discussion). Visual orienting has therefore been of particular interest in the study of ADHD (Huang-Pollock & Nigg, 2003). It refers simply to the location in space at which processing is facilitated. Reflexive orienting (e.g., to a sudden onset of light) is guided by a posterior neural network that includes the parietal cortex as well as subcortical and thalamic structures, known collectively as the posterior attention system. However, once we are oriented to a location in space, we still have a limited capacity to process the available information. Thus, we must further select those objects at a given location to which we will attend. When there is too much information for deliberate or cognitive processing to handle, selection of objects occurs relatively early in the stream of information processing, in an automatic bottom-up manner (Lavie, 1995; Table 9.2). Selection in this case is based on surface or perceptual features such as movement, color, or line orientation, as noted above (Triesman & Gelade, 1980). Neurally, this “early selection” is also related to a posterior cortical-subcortical network. Thus, for heuristic purposes, we group (1) automatic spatial *orienting* and (2) early (perceptual) *selection* together, as two related domains of the posterior attention network.

Anterior Attention System

Visual orienting and object selection both can also occur in a top-down strategic manner. In that instance, they share the qualities of requiring mental resources, being fairly responsive to deliberate and strategic considerations, and being associated in neuroimaging studies with the anterior neural networks that include the anterior cingulate cortex (Posner & Peterson, 1990). We thus group strategic orienting and selection together in Table 9.2 as probes of an anterior attention system. They may be thought of as components of executive function that are specifically attentional. Strategic orienting occurs in response to a sign,

TABLE 9.2 Three Attentional Brain Networks and Suggested Operations Derived from Different Attention Models

Neural System	Functional Cognitive Mechanisms
Posterior Attention System	Reflexive orienting Early or perceptual selection
Anterior Attention System	Strategic orienting Late or cognitive selection Conflict detection
Vigilance System	Alerting Sustained attention

such as an arrow pointing to a target. Strategic object selection occurs late in the stream of information processing (called “late selection”), where it is based on cognitive meaning and the strategic importance of the material (one classic example is a Stroop task). Late selection can be thought of as an executive function in that it is deliberate, requires resources, and is supported by the anterior neural networks noted earlier, in parallel with strategic orienting (Table 9.2). Note that further suggestions for fractionating the executive domain of attention are extensive and include sub-elements such as working memory capacity, cognitive interference control, and set shifting (Mirsky & Duncan, 2001; Table 9.2).

Conceptualized this way, orienting and selection are both guided by relatively automatic or reflexive processes, as well as by relatively strategic or deliberate processes. Developmentally, posterior and anterior processes reveal distinct trajectories in infancy and childhood, as well as late adulthood. Posner and Rothbart (2000) point out that in early infancy, reflexive orienting to cues guides attention, even before reactive (affective) responding and well before deliberate directing of attention can be observed (the latter emerges during the toddler years). Likewise, Huang-Pollock, Carr, and Nigg (2002) compared children in second through sixth grades on a computerized selection task to show that late selection was progressively more mature in the older groups. Even sixth graders were still well below adult level capabilities, although they were notably better than fourth graders. In contrast, early perceptual selection was essentially fully mature, at adult levels, even in the second graders (Huang-Pollock et al., 2002). These types of data are all consistent with the proposition that relatively automatic attentional processes develop earlier and complete their development at a much younger age than do anterior or cognitively demanding attentional processes, exemplifying the idea that neural development proceeds along a posterior-to-anterior gradient. This pattern also is consistent with the frontal cortical neural networks’ gradual maturation throughout adolescence, with myelination and synaptic pruning ongoing through early adulthood (Benes, 2001).

Vigilance and Alerting

Moderating the posterior and anterior attention systems are state regulation functions referred to by Posner and Peterson (1990) as a *vigilance* system (see Table 9.2). This system is responsible for arousal/alerting and vigilance/sustained attention. Alerting, which refers to the ability to respond appropriately and efficiently to phasic stimuli, is

related to the older concept of *arousal*, which also referred to degree of alertness (Mirsky & Duncan, 2001). The nuances of arousal, alerting, and the associated term *activation* (which pertains to readiness for motor response) are discussed later. For now, we refer to alerting or arousal interchangeably. However, distinct from those, this system is also responsible for maintaining task focus over time, called *vigilance* (Posner & Peterson, 1990) or *sustained attention*; (Mirsky & Duncan, 2001). Debate continues as to whether alerting/arousal and vigilance/sustained attention constitute not just distinct operations, but distinct neural networks (Parasuraman, Warm, & See, 1998). For simplicity, we group arousal/alerting and vigilance/sustained attention together as two major operations of a vigilance system (following Posner & Peterson, 1990). Also for simplicity, we refer to arousal as a single process when summarizing the ADHD literature, although it is probably not unitary either (Derryberry & Rothbart, 1988).

Developmentally, arousal is an important characteristic even in infants and is considered perhaps the earliest hallmark of self-regulation (Olson, 2002). Crucially, regulation of arousal from very early in life is heavily dependent on caregiver responsiveness. For example, a large body of literature notes the difficulty in arousal regulation experienced by children with insecure attachments to their parents when in stressful situations, and some evidence suggests that this relation is not merely “temperament driven” but is at least in part a reflection of the quality of the parent-child interaction (Olson, 2002; Schore, 1994). Similarly, early sleep regulation is partly temperamental and partly related to parental monitoring (Dahl, 1996; Peirano, Algarin, & Uauy, 2003). Whether these different examples of arousal are all addressing the same underlying processes is an open question. We conceive of the vigilance system and arousal as crucial in early development but as continuing to mature throughout childhood and adolescence. They moderate other attention and impulse control operations.

Conclusion: Three Core Attention Networks and Their Subfunctions

Because the important distinction between automatic and deliberate attention suggests differential activation of posterior versus anterior attention networks, we can group selection and orienting operations into (1) multiple, early developing, relatively automatic processes of the posterior attention system and (2) multiple, later developing, relatively deliberate operations of the anterior neural network related to executive functioning, selective attention, and

working memory. The third moderating system, the vigilance network, is distinct from both of these and includes multiple operations as well, including arousal (phasic) and sustained attention. Overlooking many other models of attention in the interest of space, we can illustrate what is known about the psychopathology of ADHD in terms of these three basic networks governing attention, and their subfunctions. In relation to ADHD, we thus first discuss the early maturing, relatively automatic processes of (1a) reflexive visual-spatial orienting and (1b) early (perceptual) object selection. We second consider the later maturing processes related to executive functioning or “controlled processing” (Monsell & Driver, 1998), which include (2a) strategic or deliberate visual-spatial orienting, (2b) late (cognitive) object selection, and (2c) operations of working memory, as well as supplemental information on the concept of (2d) “set-shift.” Third, we take up the moderating or “state regulation” capacities of (3a) alerting/arousal and (3b) vigilance, ending with consideration of the related concept of *activation*. Before we take up the ADHD findings, however, we more formally conceptualize impulse control.

Impulse Control: Conceptual Framework

Impulse control can also be thought of as being regulated by multiple, interrelated behavioral and neural systems in the child, in addition to the interpersonal and incentive context in which the child is acting. Within the child, we can simplify the descriptive options for a moment by considering a deceptively simple question: How does a behavior (e.g., an impulse, or a response that was about to be carried out) get stopped, interrupted, suppressed, or inhibited? Developmental studies suggest that either (1) more than one process is involved in controlling impulses in this way, or (2) an underlying control mechanism becomes able to interrupt different kinds of behavior at different points in development. For example, Dempster (1993) noted that the ability of children to suppress or inhibit motor movements develops earlier than the ability to suppress or inhibit word meanings in language use, although whether this is due to the differential rates at which motor and language skills develop or to distinct control operations coming online remains uncertain.

Consider further that impulses can arise in at least two basic ways: via an immediate incentive (reaction) that invites approach or a long-term goal that comprises a series of “next steps” (strategic planning). Correspondingly, impulses to action (motor or vocal response) are *controlled* by two distinct higher-order neural networks or mechanisms (Nigg, 2001; Rothbart & Bates, 1998). First is the re-

active or motivated suppression of response, which is relatively spontaneous (Gray & McNaughton, 1996; Kagan, 1997). A simple illustration involves stopping what one is doing due to anxiety about a new person or a new event that appears. For example, a child may stop playing if an unfamiliar child walks into the room because of mild anxiety about the unknown that this child represents. This process operates in response to the elicitation of anxiety or fear (immediate, short term, and relatively automatic), related to cues for uncertainty or for imminent punishment. When serving to interrupt a behavior, it can be termed *reactive* response suppression (or reactive behavioral inhibition; this has also been called by us “motivational inhibition”; see Nigg, 2000). Note that whereas extreme fear may lead to a freeze response (suppression of all behavior), when anxiety is operative, this same process also redirects attention, including both spatial orienting and filtering or object processing. This redirection exemplifies the close relation of attention and impulse control in moment-to-moment behavior. Along with anxiety, strength of incentive *approach* (excitement to a reward cue) also influences impulsivity. In other words, the stronger the original approach tendency, the more difficult it is for anxiety to interrupt it. Thus, impulse control also can fail because such approach processes are dysfunctionally strong. The *relative* strength of approach and behavioral inhibition processes has thus been proposed as further etiology of impulsivity (Newman & Wallace, 1993).

The second general control process is characterized by the involvement of strategic (i.e., deliberate, long-term) responses to events and their relation to long-term goals, closely connected to the now familiar construct of executive functions. This type of control can thus be termed *executive* or deliberate response suppression (referred to as executive inhibition in Nigg, 2000). It refers to the deliberate suppression of a response in order to achieve a later, internally represented goal (e.g., not scratching a mosquito bite so that it will heal faster; managing not to interrupt a long-winded colleague so as to fulfill a personal resolution to be more patient). Neurally, the specific suppression of a motor response for strategic reasons (a hallmark of cognitive control) is related to a subset of the associated frontal networks, namely, a neural loop that includes the prefrontal cortex (in particular, orbitofrontal and right inferior frontal, especially inferior frontal gyrus; Aron, Fletcher, Bullmore, Sahakian, & Robbins, 2003), basal ganglia (especially the caudate), and thalamus (Alexander, Crutcher, & DeLong, 1991; Middleton & Strick, 2002). It is modulated by frontal-cerebellar loops throughout development (Diamond, 2000; Middleton & Strick, 2001).

The reactive and executive processes likely are dialectically related developmentally and in action selection, and both are closely involved in all aspects of behavioral regulation. These two processes thus likely modulate each other and can override each other in particular contexts (Nigg, 2001). For example, to achieve an important goal, one might overcome fear of a possible punishment (a new professor anxious about speaking in front of colleagues does so anyway in order to explain his work). At the same time, anxiety might interrupt deliberate processes (the new professor forgets his next point due to the intrusion of a worry about how the talk is going).

As was the case for attention, our heuristic two-process model of impulse control is in some respects too general, in that these two core processes are each amenable to further differentiation. For instance, in the reactive domain, Asendorpf (1990) followed preschool children for several years. Two kinds of *reactive* behavioral inhibition were coded. The first was inhibition when meeting new children, or inhibition to social novelty, which *weakened* with development over the preschool period. In other words, children were less fearful when meeting new children as they matured during preschool. The second type of inhibition was stopping a behavior based on a learned negative association, or inhibition in response to punishment cues. It *strengthened* as the children developed: Children were more effective at stopping behavior contingent on a warning of punishment as they matured. This study suggests that two kinds of reactive behavioral inhibition, meeting strange peers versus responding to learned punishment cues, may be related to distinct developmental mechanisms that follow different behavioral trajectories during the preschool period. Failure of either process to develop within an acceptable range might lead to later problems with impulse control.

Furthermore, the preceding discussion of reactive control emphasized anxiety response and alluded only briefly to fear. An extreme fear or “panic” response is widely considered to dissociable from anxiety (Depue & Lenzenweger, 2005; Gray & McNaughton, 1996). This fear/panic or fight-flight system can lead to the “freeze” response and then to vigorous action. Gray’s (1971) initial suggestions about the role of the fight-flight system in disinhibitory psychopathology were long overlooked but have recently been revived (Beauchaine, Katkin, Strassberg, & Snarr, 2001). In all, reactive behavioral suppression is not strictly unitary, even though we generally treat it as such for simplicity.

Similarly, in the domain of strategic control, the degree of fractionation of functions remains in debate. For example, (1) stopping a primary, intended response on the basis of new information, (2) suppressing a competing and never

intended response, or (3) inhibiting a reflex response may be construed as distinct or similar, depending on the conceptual framework (see Barkley, 1997; Friedman & Miyake, 2004; Miyake et al., 2000; Nigg, 2000). We note, however, that the temporal relations of cognitive and motor functions suggest some differentiation. For example, holding a goal in working memory may be distinct from carrying out a goal-directed behavior or resisting interference from a competing, tempting response (Zelazo et al., 2003).

As implied in the preceding, it is important to recognize that reactivity can change with developmental context and experience. For example, some children who are behaviorally inhibited in preschool (i.e., highly reactive or anxious in novel situations) do not show this behavior pattern in elementary school, whereas other children show stability in this trait (Kagan, 1997; Kagan & Snidman, 2004). The socialization context may prove crucial for helping some children to overcome their proclivity for anxious inhibition (Kagan, 2003). Furthermore, and unsurprisingly, executive control continues to develop from preschool to childhood and then into adolescence and on into adulthood. In particular, the ability to strategically control an impulse undergoes consolidation from the preschool to early school years (Carver, Livesey, & Charles, 2001), and then continues to steadily improve into middle to late adolescence (Bedard et al., 2002; Williams, Ponesse, Schachar, Logan, & Tannock, 1999). Such developmental trends are consistent with the continued maturation of frontal-subcortical neural networks during development, maturation that does not terminate even with the end of adolescence.

As a final caution, we note that other processes are involved in behavioral control as well. For one thing, children with behavioral problems, such as those diagnosable with ADHD, often think up rather unexpected impulses that might not occur to the average child; this phenomenon may have to do with an unusual learning history or motivational structure that is outside of our framework here. In addition, central and peripheral motor systems in the child may have experienced delays in development, compounding efforts at motor impulse control (Piek et al., 2004). Finally, as we highlight later, language development plays an important part in impulse control during development. Nonetheless, for the most part, when we discuss impulse control we focus on two related processes: reactive and strategic interruption of a potential response.

Final Overview Comment

As a final note on this preliminary conceptual section, many other models and conceptions could be discussed in

an encyclopedic review of self-regulation, attention, or impulse control, including several that have been influential in the psychopathology literature, such as “hot and cool” delay of gratification (Metcalf & Mischel, 1999), ego control (Block & Block, 1980), activation and effort (Pribam & McGuinness, 1975), extraversion (Eysenck & Eysenck, 1985), behavioral inhibition (Quay, 1988), regulation (Calkins & Fox, 2002; Kopp, 1982), response regulation (MacCoon, Wallace, & Newman, 2004; Newman & Wallace, 1993), and key socialization models (Greenberg, Speltz, DeKlyne, & Jones, 2001; Kopp, 1982). Rather than survey all of these or their many overlaps with our perspective (for additional review, see Douglas, 1999; Nigg, 2000; Rothbart & Bates, 1998; Sergeant, Oosterlaan, & van der Meere, 1999), we emphasize the basic two-factor heuristic just presented that partially integrates temperament with models from cognitive science.

With these qualifications in mind, we consider the functional component systems that can be roughly assigned to distinct distributed neural networks. We consider these networks first from the perspective of attention and then with regard to impulse control. Whereas we initially isolate these functions for expository purposes, the relationship among the regulatory domains will be important when we subsequently consider developmental pathways.

ATTENTION AND PSYCHOPATHOLOGY IN RELATION TO ATTENTION-DEFICIT/ HYPERACTIVITY DISORDER

We now consider whether attention may be a core mechanism that is impaired, in some way, in children or adults with what are termed attentional disorders. To do so, we view attention from several angles, working through the posterior network, anterior network, and alerting/vigilance.

Early Developing Processes: Posterior Attention Network and Attention- Deficit/Hyperactivity Disorder

We noted that the posterior attention network subserves easily studied visual functions, including reflexive orienting and perceptual selection. Because ADHD, at least in the Combined subtype form (ADHD-C), is often associated with problems in executive functioning (e.g., Barkley, 1997), we might expect that ADHD-C would *not* be associated with posterior attentional problems. Most evidence over the past 10 years has confirmed this guess. With regard to orienting, we recently reviewed all published data

on visual-spatial orienting that relied on the widely used, computerized orienting task, finding no consistent meta-analytic evidence for such a problem in children with ADHD-C, across 14 studies in the past decade and a half (Huang-Pollock & Nigg, 2003). Intriguing, isolated findings of posterior shift (not to be confused with executive set shifting, later) or disengage problems simply could not be replicated.

With regard to selection, historically the data have argued against a perceptual selection problem in ADHD-C (Berman, Douglas, & Barr, 1999; McIntyre, Blackwell, & Denton, 1978; Sergeant & van der Meere, 1988; Sharma, Halperin, Newcorn, & Wolf, 1991). Many such investigations, however, lacked systematic control of perceptual load in addition to other limitations (see critique by Douglas, 1999). The issue of load in particular was a potentially important gap in light of subsequent theories of load and selection (Lavie, 1995). Yet, a recent investigation controlled perceptual load more systematically using these newer paradigms, again with no evidence of perceptual selection problems in ADHD-C (Huang-Pollock, Nigg, & Carr, 2005).

In the face of growing consensus that the posterior attention network functions are not primarily involved in ADHD-C, theorists have suggested that the posterior attention network may be a mechanism in children with ADHD Inattentive type (ADHD-I; Goodyear & Hynd, 1992; Milich et al., 2001). Very few data address this possibility formally. However, the few data on automatic visual-spatial orienting in ADHD-I do not support deficits in this domain (Huang-Pollock & Nigg, 2003), casting doubt on the potential for that particular probe of a posterior attention system. Similar results emerged in a study that varied perceptual load to isolate early selection (Huang-Pollock et al., 2005). Yet, studies are so few that the status of posterior attention network abilities in ADHD-I remains uncertain.

At the same time, there has been substantial concern in the nosology literature that the ADHD-I type may not be well-specified. In particular, it may be that items tapping sluggish cognitive tempo (a tendency of a child to be “spacy,” underactive rather than overactive, and have low energy) are important to recognize when defining a subgroup with purely inattentive forms of ADHD (C. Carlson & Mann, 2002; McBurnett, Pfiffner, & Frick, 2001). Indeed, in *DSM-IV*, the inattentive type includes, by definition, children who are overactive (but just below the threshold for ADHD-C) plus children who are clearly underactive. The latter group may be those most affected by a posterior attention system dysfunction (see Milich et al.,

2001). Huang-Pollock et al. (2005) reported some intriguing possible support for this idea in their investigation of perceptual load, but the sample was small. More study of this idea is likely to be one element of future work in the field.

Notably, in contrast to the hypothesis that ADHD-I may be related to underfocused selection in the posterior system, it has also been suggested that automatic overselection ("overfocused" attention) may be a mechanism involved in psychopathy (Hiatt, Schmitt, & Newman, 2004; MacCoon, Wallace, & Newman, 2004; Newman & Wallace, 1993). In view of the possibility that a subgroup of children with severe hyperactivity, impulsivity, and aggression may be at risk for future psychopathy (Lynam, 1998), further study of this possibility will be of interest.

Summary

Various probes of the posterior attention system, such as automatic visual-spatial orienting and early perceptual object selection, suggest that this system is not promising as a locus of core dysfunction in ADHD-C. However, a subset of children with ADHD-I may have problems in that domain; data are too sparse to draw conclusions at this point. Key limitations in this work to date include insufficient empirical study of ADHD-I and limited consideration of motivation as a contributor to automatic attention allocation. Future work that probes such reactive processes (e.g., through priming designs) will be of interest, as will future work on the inattentive subtype. Other models not discussed here may also be important, such as Newman and colleagues' (e.g., MacCoon et al., 2004) discussion of the role played in self-regulation by the ability to detect warning cues.

Later Developing Processes: Anterior Attention Network and Attention-Deficit/Hyperactivity Disorder

We now move to perhaps the most heavily studied domain of attention in ADHD, that of executive attention related to the anterior attention network. It has been often theorized as centrally involved with ADHD-C. Several abilities are included, depending on which model of executive control one prefers. Drawing upon the aforementioned cognitive models as well as related neuropsychological models (e.g., Mirsky & Duncan, 2001; Pennington & Ozonoff, 1996), we organize our remarks in relation to a set of four basic abilities: (1) late selective attention or interference control, (2) strategic attentional orienting, (3) set shifting, and (4) working memory (and its components, including short term memory).

Late Selective Attention/Interference Control

Late selection, or interference control, figures prominently in many theories of ADHD (Barkley, 1997; Berger & Posner, 2000). The most classic test of anterior attentional selection, or interference control, is the Stroop task (MacLeod, 1991). One must name the ink color of color-words (e.g., the word "red" printed in green ink); reading the word is more automatic than naming the color, so interference results. Both qualitative (Nigg, 2001) and quantitative (Homack & Riccio, 2004; Van Mourik, Oosterlaan, & Sergeant, 2005) reviews have concluded that Stroop interference is at most minimally impaired in ADHD-C in childhood. However, the null findings may be related to methodological limitations. Most saliently, studies relying on the paper-and-pencil version of the Stroop task, and thus utilizing a single "total items within 45 seconds" score timed with a stopwatch, have not yielded evidence for large problems in interference control on the part of participants with ADHD, apart from the slow naming speeds characteristic of this disorder (reviewed in detail by Nigg, 2001). Yet, investigations using computerized interference control tasks, which enable calculation of reaction time for each item and then averaging all of these individual item reaction times, have had more success (Carter, Krener, Chaderjian, Northcutt, & Wolfe, 1995; Jonkman et al., 1999), though not unequivocally (Huang-Pollock et al., 2005). Overall, then, interference control has yet to be clearly confirmed as a replicable dysfunction in ADHD-C.

This ability is also factored in psychometric studies with other neuropsychological tests, such as the Trailmaking test (Mirsky & Duncan, 2001), which requires rapidly tracing a line between alternating letters and numbers (e.g., 1-a-2-b-3-c). Although such a grouping may be debatable (Pennington & Ozonoff, 1996, group Trailmaking under "set shifting," next section), the Trailmaking test shows modest ADHD-related deficits (e.g., Nigg, Blaskey, Huang-Pollock, & Rappley, 2002) with meta-analytic effect size estimated at $d = .55$ across 14 investigations (Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005). Yet its demand for ongoing motor control and set shifting call into question the Trailmaking test's purity as evidence of an attention problem per se.

Set Shifting

Although not featured in most cognitive neuroscience models, set shifting is regularly implicated in many neuropsychological tasks. Aside from the Trailmaking test as a possible measure, one classic neuropsychological measure

of this concept is the perseveration errors score on the Wisconsin Card Sort Test (WCST; Mirsky & Duncan, 2001; Miyake et al., 2000). The WCST requires children to adopt a response set (e.g., match cards by color) and then to switch to a different response set (e.g., match cards by shape). Perseverating on the initial response set is viewed as a weakness in set shifting. This measure likewise shows only modest effects in ADHD: As recently reported, the meta-analytic effect size across 24 studies of ADHD was $d = .46$, with the majority of individual investigations failing to find a significant effect (Willcutt et al., 2005). The largest WCST studies accordingly provide mixed results (Houghton et al., 1999; Klorman et al., 1999; Pineda, Ardelli, & Rosselli, 1999; Willcutt et al., 2001). However, as a measure of set shifting, the WCST is limited by a reliance on errors rather than reaction times (error scores are notoriously problematic in terms of psychometric properties; see M. B. Miller, Chapman, Chapman, & Collins, 1995) and lacks the precision of millisecond reaction time probes. Alternative error measures of set shifting ability may show an ADHD-related deficit (Koschack, Kunert, Derichs, Weniger, & Irle, 2003) but face the same psychometric limitations. Therefore, recent studies have borrowed task-switching designs from cognitive psychology that rely on reaction time measures. Although varying in detail, these designs all induce a response set and then measure reaction times when the primary response set must be changed; they can monitor dual-task performance (performance cost of doing two things at once) or switching costs (see Pashler, 1998). Application of these more refined paradigms to ADHD has barely begun. Initial studies provide some evidence of rapid, controlled shifting deficits (Cepeda, Cepeda, & Kramer, 2000; Hollingsworth, McAuliffe, & Knowlton, 2001; Oosterlaan & Sergeant, 1998b; Perchet et al., 2001; Schachar, Tannock, Marriott, & Logan, 1995), but studies to date are too few and varying in method to allow firm conclusions about the magnitude of the effect.

Working Memory

Working memory is a vast topic in itself, yet it is clearly related to attention because it is also described as a limited-capacity system with two basic elements. The first element, commonly referred to as the “central executive” (Baddeley & Hitch, 1994) or “working memory capacity,” is viewed as a domain general ability that essentially taps the same construct as the anterior attention network discussed earlier (Engle, 2001, 2002). It involves the ability to protect and manipulate information in mind, and likely depends in part on dorsolateral-prefrontal cortex (Kane &

Engle, 2002). The second element entails domain-specific, short-term memory modules for temporarily holding information. The most common division of these is into the visual sketch pad (visual working memory) and the phonological loop (speech-based information or verbal working memory; Baddeley & Hitch, 1994). At least 20 experimental studies have looked at working memory and related abilities (short term memory, planning) in ADHD in recent years. These are most interpretable if sorted into verbal versus spatial domains.

In the verbal domain, Tannock, Ickowicz, and Schachar (1995) noted ADHD-related deficits on a serial addition task, which were improved by medication only for those children with low comorbid anxiety. Others also found that children with ADHD (usually ADHD-C) performed worse than controls on verbal working memory tasks (McInerney & Kerns, 2003; Stevens, Quittner, Zuckerman, & Moore, 2002). Such effects, however, may depend on the particular measure used and do not appear to be robust to covarying the influence of comorbid symptoms (McInnes, Humphries, Hogg-Johnson, & Tannock, 2003; Sonuga-Barke, Dalen, Daley, & Remington, 2002). In their meta-analysis of digit span backward and sentence span tasks, Willcutt et al. (2005) reported a composite effect size of $d = .55$ across 11 studies; similar results were reported by Martinussen, Hayden, Hogg-Johnson, and Tannock (2005). Notably, Martinussen et al. observed a similar effect size for short term memory (e.g., digit span forward) and working memory (e.g., digit span backwards). In all, verbal working memory deficits in ADHD appear to be modest in magnitude.

Measures of visual-spatial working memory show more dependable ADHD-related effects. This appears on three kinds of tasks: (1) planning tasks (such as Tower of Hanoi), (2) traditional working memory tasks such as spatial span backwards, and (3) short-term memory tasks (e.g., spatial span forwards). In planning tasks (e.g., Tower of Hanoi or Tower of London, in which the child must rearrange discs or balls on wooden pegs by mentally looking ahead at the necessary moves; Klorman et al., 1999; Nigg, Blaskey, Huang-Pollock, & Rappley, 2002) or the self-ordered pointing task (Shue & Douglas, 1992), meta-analytic effect sizes are robust, with $d = .69$ for 6 studies using the Tower of Hanoi (but only $d = .51$ for 6 studies with the Tower of London; Willcutt et al., 2005). However, these tasks appear to involve reasoning as well as working memory. In the second type of task (working memory), Martinussen et al. (2005) found $d > 1.0$ in a meta-analysis of 7 studies of spatial span backwards or similar tasks. Third are short-term memory tasks that tap storage capacity but not executive control or protection,

using tasks such as the spatial span of apprehension (Karatekin & Asarnow, 1998; McInnes et al., 2003) or the CANTAB spatial working memory task (Barnett et al., 2001). These types of measures yielded a composite effect size of $d = .85$ across 9 studies (Martinussen et al., 2005). Thus, whereas ADHD clearly involves some type of difficulty in spatial short term or working memory, it is unclear to what extent difficulties in visual working memory are due to difficulties with the protection of working memory (interference control, or anterior attention) versus the functioning of the spatial working memory scratch pad per se (see Martinussen et al., 2005). The picture is compounded by evidence that visual working and short term memory tasks both may tend to entail executive control, and more so than do auditory tasks (Miyake, Friedman, Rettinger, Shah, & Hegarty, 2001). For now, it may be most parsimonious to view the ADHD difficulty in these studies in terms of the executive control of attention (protecting working memory; or in other words, the working memory “central executive”), but more differentiated work will be of interest. The large effect sizes apparent in these initial studies are provocative, and their magnitude after more studies have been completed will be of interest.

Summary

Evidence for a modest anterior attention dysfunction in ADHD exists from a wide range of neuropsychological investigations, although it is unclear that such deficits are as robust or large as might be needed for a convincing core deficit in ADHD. In particular, effect sizes on widely studied clinical neuropsychological measures, such as the Wisconsin Card Sort and the Stroop test, are of small to at most medium magnitude. However, aspects of working memory or short term memory appear to be more clearly involved, at least in the spatial domain. Newer, more refined measures of cognitive selection and working memory that capitalize on reliable reaction time measures or that emphasize components of working memory (e.g., visual working memory) may clarify matters in coming years.

Moderating Processes: The Vigilance Attention Network and Attention-Deficit/Hyperactivity Disorder

Recall that the vigilance system (Posner & Peterson, 1990) is responsible for establishing and maintaining an alert state (“ready for anything”). Lapses in this attention function are apparent to anyone who is tired or sleepy; they are also salient in such medical conditions as epilepsy and narcolepsy (Mirsky & Duncan, 2001). Vigilance depends on a

network of neural structures that include the noradrenergic system originating in the locus coeruleus, the cholinergic system of the basal forebrain, the intralaminar thalamic nuclei, the right prefrontal cortex (Parasuraman et al., 1998; Posner & Peterson, 1990; Rothbart, Derryberry, & Posner, 1994), and possibly the ascending reticular activating system (Mirsky & Duncan, 2001; the latter is related to wakefulness). We noted two distinct functions: phasic *alerting* to a stimulus (Berger & Posner, 2000; called “arousal” by Pribram & McGuinness, 1975, and “stabilize” by Mirsky & Duncan, 2001), followed by tonic sustaining of attention to the stimulus, called *vigilance* (Posner & Peterson, 1990) or “sustained” attention (Mirsky & Duncan, 2001). Grouping these functions together is conceptually helpful (Posner & Peterson, 1990), although their degree of neuroscientific linkage remains unclear (see Mirsky & Duncan, 2001; Parasuraman et al., 1998).

A complication for readers of the ADHD literature is that the concept of tonic vigilance is related in some models to still another concept, that of “activation” (Pribram & McGuinness, 1975), a term itself often used in differing ways in the ADHD literature and in the developmental and temperament literature. The lack of isomorphism in handling “activation” across theories is related to distinct historical streams of thought (Strelau, 1994). One stream, exemplified by Gray (1982), arose from research on temperament and learning theory reaching back through the work of Eysenck to Pavlov’s early conceptions of learning, in which activation was closely related to reward responding. The second stream, exemplified by Posner and Peterson (1990) and Pribram and McGuinness (1975), arose from the cognitive sciences and information-processing approaches, which de-emphasized incentive response and emphasized global response readiness and attention. Table 9.3 summarizes the scientific traditions that distinguish arousal from activation in these two different ways. As a result, one current thread of theorizing about ADHD draws on temperament and learning theory (and, more recently, associated animal models of ADHD), thus emphasizing reward response (e.g., Sagvolden et al., 1998, 2005). Another thread of ADHD theorizing draws on cognitive and information-processing theory and emphasizes impaired demand-response preparation generally (e.g., Sergeant et al., 1999).

We distinguish these two meanings of activation because they sometimes make different predictions (e.g., regarding importance of reward) and have distinct theorized neural concomitants. Thus, the reward-based activation concept is related to dopaminergic reward pathways, whereas the vigilance system under discussion in this section is related to noradrenergic projections. We therefore

TABLE 9.3 Parallel Yet Distinct Historical Conceptions of State Regulation by Arousal and Activation

	Arousal/Alerting Marker		Activation/Approach/Vigilance Marker	
	Neural	Response	Neural	Response
<i>Temperament Theories of Arousal-Activation</i>				
1. Eysenck (1967)	RAS	Extraversion	Autonomic response	Neuroticism
2. Gray (1971)	RAS	After incentive cue increase next response intensity	Ascending DA fibers to basal ganglia, limbic, and prefrontal (mesolimbic DA)	Motor response to reward cue
<i>Information Processing Theories</i>				
1. Pribram and McGuinness (1975)	RAS, amygdala hypothalamus	Time-locked, phasic responding, heart rate deceleration, <i>CPT d'</i>	Basal ganglia striatum	Tonic physiological change; in vigilance tasks, <i>CPT beta</i>
2. Tucker and Williamson (1984)	Right lateral NA neurons	For any stimulus input, enhance signal; noise detection	Left lateralized DA projections	Preparation for motor response
3. Posner and Petersen (1990)	Right lateral NA neurons frontal/parietal	Phasic alerting to new signal	Right alerting network	Tonic vigilance to ongoing signal; sustained RT rate over time

Notes: DA = Dopaminergic brain projections; NA = Noradrenergic brain projections; RAS = Brain stem to cortex ascending reticular activating system and associated corticoreticular neural loop. D-prime and beta refer to parameters on the continuous performance test, which is a laboratory cognitive task.

consider activation in two different ways. First, we consider it as a demand-response function along with our consideration of the vigilance system in the present section, as Activation. We do so even though, as noted in Table 9.3, the neural instantiation of this response-readiness type of activation has been disputed and may not be in the same neural system as vigilance or sustained attention as we have described it. Second, we consider responsiveness to reward incentive cues in a later section, under the rubric of reactive or motivational response.

Collectively, these functions are sometimes referred to as *state regulation* rather than attention functions (Sergeant et al., 1999). Here, we adopt the framework of Posner and Peterson (1990; Table 9.3), while highlighting key divergences related to other perspectives. Our main theme is that the data on these two broad types of functions—alerting and sustained attention—are distinct in relation to ADHD.

Alerting

Alerting refers to initial response to a stimulus. It involves the ability to prepare for what is about to happen. It is relevant the instant a warning is received, or when there is a need to be ready to respond without warning. An example might be waiting during a short-answer test for the next question from the teacher, or waiting in a track meet for the starting gun to sound. It is closely related to the older concept of cortical *arousal*, and for our purposes those two terms can be put together. We view arousal as a right brain

lateralized process of activation by noradrenergic neurons. It responds to stimulus input and prepares to take advantage of new information by enhancing the signal:noise ratio for novelty detection (Posner & Peterson, 1990). Recent theories and data have used the term “alerting” to refer to specific deficits related to ADHD (Berger & Posner, 2000), whereas classic theories of ADHD emphasize a deficit in cortical “arousal” (Satterfield, Cantwell, & Satterfield, 1974; Zentall & Zentall, 1983) or, concomitantly, disruption in ascending noradrenergic neural systems that facilitate signal:noise detection (McCracken, 1991).

Alerting can be assessed in several different ways, most of them relating to reaction time or physiological response in the first seconds after encountering a stimulus of some kind. Thus, with regard to reaction time and errors, an effective alerting system prepares for a rapid, accurate response. As a result, when alerting is impaired, we predict that children will make slow, inaccurate responses when fast responses are required, in the same way that a tired driver has slower reaction times to a sudden traffic stop. Thus, in the laboratory, a deficit in alerting (or phasic arousal) is usually marked by poor performance (slow, variable response times) either on a series of single abrupt-onset trials (e.g., detect the light the moment it appears and touch the key as quickly as possible) or poor performance from the very beginning of a reaction time task. At the same time, when waiting or reflection is required, someone who is not alert or who has low cortical arousal would be

expected to have difficulty waiting, because such waiting and reflecting requires appropriate arousal; in that context, our tired friend would respond too hastily.

Therefore, two different kinds of performance problem are consistent with an alerting deficit: slow and variable responses to fast tasks, and hasty, inaccurate responses to slow-careful tasks. Both kinds of response patterns are typical in impulsive children and children with ADHD. Failures in this system therefore could account for inability to regulate behavior or attention effectively in ADHD. (Note that *excess* arousal would lead to a classic impulsive style of hasty, inaccurate responding, but not slow, variable responses on fast reaction time tasks; therefore, the predominant view regarding ADHD is that it involves low rather than high arousal. Other forms of impulsivity may be precipitated by high arousal.)

The evidence for slow and variable responses, and poor responses from the very beginning of reaction time tasks, comes from several reviews and meta-analyses. This pattern was evident in a detailed review of the early literature (Sergeant & Scholten, 1985), a meta-analysis of this function in 8 studies using the stop task (Oosterlaan, Logan, et al., 1998), and recent, large-sample studies (Swanson et al., 2000). However, a review of orienting studies did not observe a dependable slow and variable response pattern across all studies, even though most studies did observe that effect (Huang-Pollock & Nigg, 2003). Leth-Steensen, Elbaz, and Douglas (2000) also reported a sophisticated analysis of variable response profiles in ADHD, emphasizing that children with ADHD make an excess of very slow responses, consistent with variable attention or low arousal.

Other evidence is also consistent with this idea. For example, the continuous performance task (CPT) d' parameter, a signal-detection measure reflecting sensitivity to the difference between a target and a nontarget (Lachman, Lachman, & Butterfield, 1979), shows an aggregate ADHD-related deficit in meta-analytic reports (Losier, McGrath, & Klein, 1996). This finding can be interpreted as evidence of an arousal or alertness dysfunction. Further, EEG slow wave findings and early evoked response potential (ERP) tend to be consistent with an arousal dysfunction. Among the first efforts to use contemporary definitions of ADHD and viable EEG methods was conducted by Satterfield and colleagues (Satterfield et al., 1974; Satterfield & Dawson, 1971). Recent electrophysiological work has often, though not unequivocally, been supportive (Brandeis et al., 1998; Monastra et al., 1999; Silberstein et al., 1998). A salient finding entails an excess ratio of theta:beta activity, or excess relative slow wave activity, in ADHD (for a review of EEG, see Barry, Clarke, & Johnstone, 2003a; for ERP, Barry, Clarke, & John-

stone, 2003b). Barry et al. (2003a, 2003b) concluded that the EEG and ERP evidence both are consistent with central nervous system (CNS) hypoarousal in a percentage of children with ADHD-C as well as ADHD-I.

Caveats to this argument were pointed out by van der Meere and colleagues (Sergeant et al., 1999; van der Meere, 2002), who argued that most studies (e.g., with the CPT) failed to consider event rate and that (1) failure to find sustained attention deficits on fast-event rate CPT tasks contradicts an arousal dysfunction hypothesis and (2) many of the performance data may in fact reflect a problem in activation (see later discussion). Moreover, strategy effects (e.g., speed-for-accuracy trade-off) were often overlooked. Nonetheless, some of the evidence just reviewed is most parsimoniously viewed as indicative of arousal or alertness problems, at least in ADHD-C.

Vigilance or Sustained Attention

Broadly speaking, sustained attention refers to maintaining focus on a task over time and is thus related to the concept of activation, which refers to the ability to prepare ongoing responses in the late stages of behavioral control and organization. When referred to as "sustained attention" (Mirsky & Duncan, 2001), this ability is among the most common ideas of an ADHD core deficit, albeit one not readily supported by available evidence. In the cognitive psychology literature, it means the ability to maintain a state of alertness and wakefulness during "prolonged mental activity" (Weinberg & Harper, 1993). This notion can clearly include the child's paying attention throughout a class at school or staying focused during a sports event waiting for the cue to action. For everyone, performance shows a decrement (slower and more variable responses, more errors) as the minutes and hours go by (Parasuraman et al., 1998). ADHD-related deficits in sustained attention should result in an *excess* decline over time versus controls, yielding a group-by-time interaction.

Yet, even though children with ADHD appear to lose interest in tasks quickly, it turns out that they typically do *not* show a decline in accuracy (or in speed) over time on laboratory tasks (Sergeant et al., 1999; Sergeant & Scholten, 1985; Sergeant & van der Meere, 1990). Although reliant on interpreting null interaction findings in often small-sample studies (see Douglas, 1999), the likelihood of a true sustained attention deficit in this syndrome has been judged doubtful by most commentators in the field. Data are less plentiful for ADHD-I and ADHD-H. In the case of ADHD-C, instead of a decrement over time, these children seem to show performance deficits from the very beginning of a task or response (Sergeant &

van der Meere, 1990). This pattern suggests a problem in *alerting* or arousal, as described in the prior paragraphs, but not *sustained attention* per se. However, this finding may depend on the event rate; some data indicate that at slow event rates, a sustained attention deficit is observed (van der Meere, 2002), pointing again to the issue of weak *activation*. We now turn to this topic and consider evidence for it more directly.

Activation

Tucker and Williamson (1984) recast the time-on-task domain as *activation* (Table 9.3), dramatically shifting the conceptual emphasis to output preparation during each discrete response, rather than merely global time-on-task attentional ability (Sergeant et al., 1999). This conception affords a broader consideration of relevant evidence, now with an emphasis on motor preparation rather than attention. Indeed, left-lateralized dopamine systems are emphasized, rather than the right-lateralized system that is thought to support arousal and vigilance per se, so that some view it as an executive function (Berger & Posner, 2000). Regardless, when activation is viewed in this way, evidence is more supportive of an ADHD-related deficit. As noted earlier, Dutch scientists using time-on-task and event rate data reported that children with ADHD show normalized performance at medium event rates but weaknesses at slow and fast event rates on CPT (van der Meere, Shalev, Borger, & Gross-Tsur, 1995) and go/no go tasks (Borger & van der Meere, 2000; van der Meere & Stermerdink, 1999), leading these investigators to favor an underactivation explanation of ADHD cognitive and performance deficits (Sergeant et al., 1999; van der Meere, 2002). In other words, varying the rate at which a computer presents stimuli can moderate and nearly normalize response accuracy for children with ADHD. Further evidence for a deficit in activation or the related concept of effort comes from the difficulty children with ADHD have in producing rapid motor responses over time (Carte, Nigg, & Hinshaw, 1996). In addition, some physiological data, in particular heart rate data, appear to be supportive (van der Meere, 2002).

Caveats to this argument entail failure of some activation predictions to materialize. For example, deficits on the CPT beta parameter (an index of response bias, that is, risky versus conservative) have not been confirmed in meta-analyses (Losier et al., 1996), raising problems for an activation account. On balance, however, an activation dysfunction in ADHD remains an important possibility, with intriguing evidence of context-dependent functional deficits in children with ADHD.

Summary

The vigilance network and associated state regulation functions are extremely important for understanding ADHD. In particular, substantial evidence supports an underarousal or alerting dysfunction in ADHD, particularly ADHD-C. Contrary to popular lore, evidence fails to consistently support a sustained attention or vigilance problem in ADHD, but that conclusion depends on interpreting null findings, which are vulnerable to low statistical power, and apparently on event rate. Effects of event rate on children with ADHD suggest that a modified activation (motor preparation) account is promising. Most such research has focused on ADHD-C; the performance of other ADHD subtypes remains underinvestigated.

Attention and Attention-Deficit/Hyperactivity Disorder: Interim Conclusions

Clearly, the turning of the field to attention as a potential core deficit in ADHD in the 1970s, including renaming of the syndrome to emphasize deficits in attention, has yielded a number of important discoveries. Perhaps most surprising has been the difficulty of establishing what seems, at first glance, the most obvious candidate for an ADHD deficit, namely, a problem in sustained attention. In fact, children with ADHD appear to be less task-ready and more inattentive during all phases of task presentation, even beginning stages. As important (if less surprising) is that attentional processes associated with the early maturing posterior attention network, such as reflexive orienting and perceptual selection, are also generally spared in ADHD, at least in the visual modality and at least in children with ADHD-C. Thus, two kinds of attention—sustained attention and automatic orienting—are apparently intact in most children diagnosed with ADHD-C. Whereas the later maturing *executive* or anterior attention domain is widely viewed as important in ADHD, establishing clear and well-defined dysfunctions in executive *attention* has been elusive because of wide variations in measurement approaches and inconsistent results from traditional neuropsychological measures, resulting in small to moderate effect sizes in meta-analyses.

The safest conclusion about executive attention may be that it is a domain of only modest deficit in ADHD-C, perhaps representing a secondary rather than primary etiological dysfunction. On the other hand, arousal and related operations of the moderating noradrenergic vigilance network offer a promising candidate for a core within-child causal mechanism. Further specification and study of the idea of activation—as distinct from sustained attention and

more closely related to dopamine systems and to output or motor responding—may be fruitful and could lead to a better integration of the arousal and attention findings. Closer scrutiny of children with ADHD-I, especially those with sluggish cognitive tempo, is a key future direction for this arena of study. Finally, the intersection of motivation with arousal and executive attention findings is poorly understood in the case of ADHD. We consider motivational effects more closely in our next section.

IMPULSE CONTROL AND PSYCHOPATHOLOGY IN RELATION TO ATTENTION-DEFICIT/ HYPERACTIVITY DISORDER

As highlighted earlier, impulse control can be viewed in terms of two broad functions: reactive (motivational) and executive control. We first consider reactive control, because it is the earlier developing of these two broad mechanisms. Reactive response to incentive cues—that is, possible punishment or possible reward—comes online in late infancy (Rothbart & Ahadi, 1994). We note both reactive *suppression* of response and reward or *approach* responding as potentially important. After that, we revisit the executive domain, this time emphasizing impulse control rather than attention. Deliberate control of response begins to emerge in precursive form in the toddler years, and we highlight several kinds of evidence about those processes in ADHD throughout development. We briefly note alternative approaches to understanding the impulse control problems in children with ADHD, including motor timing and the fight-flight system.

Early Developing, Reactive Mechanisms: I. Response Inhibition and Attention- Deficit/Hyperactivity Disorder

Reactive or motivational suppression of behavior occurs in response to anxiety or fear (with variation in this suppression across anxiety and fear). Overresponding by this system can lead to internalizing and anxiety disorders (and perhaps anxious-impulsive behavior). Our main concern, however, is whether the reactive system underresponds in impulse-control disorders like ADHD, thus failing to adequately interrupt inappropriate behavior and redirect attention. This *reactive inhibitory* function depends on both the integrity of the behavioral-interruption process, which we discuss in this subsection, and the intensity of the affective states that compete with it, including excitement (positive

approach) and anger, discussed in the next subsection. Two theoretical traditions inform the temperament concept of reactive control.

In the first, Kagan and colleagues (Kagan, 1997; Kagan, Reznick, & Snidman, 1987; Kagan & Snidman, 2004) propose a temperament that is inhibited versus one that is uninhibited. Children with inhibited temperament suppressed impulses in the presence of novel social encounters (typically, novel peers) while experiencing high internal arousal. This program of research links such behavioral suppression to greater autonomic arousal and perhaps to greater limbic activation (Kagan, 1997). Over the course of development, some children with inhibited temperament develop anxiety-related difficulties (Biederman et al., 2001; Kagan, Snidman, Zentner, & Peterson, 1999), whereas those with extremes of uninhibited temperament are at risk for externalizing behavior problems (impulse control problems). As noted earlier, however, these paths are far from invariant. A notable percentage of children with inhibited temperament can move out of their classification during preschool and early childhood. Thus, this type of impulse control is detectable early on as a temperamental characteristic but may change notably with developmental context during childhood.

In the second line of thinking, Gray (1982) refers to a similar type of behavioral inhibition but with greater emphasis on the appearance of a signal for danger or punishment, though he includes the unexpected as well. An example of a cue for punishment might be when a bullying child refrains from further provocation on hearing his victim's big brother approaching, instead listening for the threat. An important point here is that when reactive suppression of impulses occurs, behavior does not stop entirely. Instead, the *current* behavior is interrupted, and *attention* is reactively and automatically redirected to the threat stimulus (Gray & McNaughton, 1996). Anxiety is the hallmark psychological concomitant of activation in this system (Gray, 1982), so that dysfunction involves low anxiety and failure to learn or adequately respond to punishment cues. Debate remains vigorous as to the critical role of response to the unexpected versus response to potential danger (Kagan & Snidman, 2004), and subsequent theories have modified Gray's model in important ways (Depue & Lenzenweger, 2005). Work on ADHD, however, has relied heavily on Gray.

Thus, following directly from Gray's thinking, theorists asked 2 decades ago whether ADHD was associated with failure to respond to punishment cues (Quay, 1988, 1997). However, most data were unconvincing (Daugherty & Quay, 1991; Milich, Hartung, Martin, & Haigler, 1994). In

fact, a central confound to this hypothesis concerns the relatively numerous subset of cases (as many as a third of children with ADHD) with a comorbid anxiety disorder. By definition, they should have an *overresponsive* reactive inhibition system. In contrast, the subset of ADHD children with low anxiety and perhaps with comorbid Conduct Disorder appears most likely to fail to respond to punishment cues (see Nigg, 2003). Perhaps as a result of failure to systematically consider these crucial comorbid conditions, experimental studies that manipulate punishment cues and examine children's response times and error rates have yielded, at best, inconsistent results for ADHD (Iaboni, Douglas, & Baker, 1995; O'Brian & Frick, 1996; O'Brian, Frick, & Lyman, 1994; Pliszka, Hatch, Borcharding, & Rogeness, 1993).

A mixed picture also emerges from physiological studies, which examine skin conductance and heart rate under varying incentive conditions, making use of sophisticated theories of central-to-peripheral nerve system responding (Fowles, 1980). Although some studies show an ADHD effect (e.g., Iaboni, Douglas, & Ditto, 1997), failure to control for associated antisocial behaviors or comorbid disruptive behavior disorders remains a limitation and results are inconsistent. Pliszka, Borcharding, Spratley, Leon, and Irick (1997) failed to substantiate an ADHD-related reactive inhibition response. However, Beauchaine et al. (2001) had more positive results using a similar approach, and O'Connell, Bellgrove, Dockree, and Robertson (2004) found abnormal skin conductance in response to errors in ADHD subjects.

Further physiological studies therefore will be of interest in the coming decade. In particular, further incorporation of specific cardiac measures such as heart rate deceleration and vagal tone may be promising to assess this aspect of functioning in ADHD. For example, Calkins and Fox (2002) reviewed a body of research indicating that poor behavioral regulation is indexed by these physiological measures. Relevant studies of children with ADHD are few.

As a final note, we point out that an alternative mechanism of behavioral inhibition would be via the fight-flight response—the fear response, as distinct from an anxiety response (Depue & Lenzenweger, 2005; Gray, 1982). This response would be expected to cause a freeze response to fear or imminent danger (suppression of all behavior) but also to trigger excessive, situationally inappropriate anger and aggressive behavior when dysfunctional (Gray, 1991). Beauchaine (2001) has theorized that this system may play a role in ADHD, and initial physiological data are intriguing (Beauchaine et al., 2001).

Summary

Overall, reactive behavioral inhibition is an important function but so far does not emerge as a likely core domain of deficit in most cases of ADHD apart from those children with early-onset, comorbid Conduct Disorder. However, research in this area remains in the early stages, with only a handful of relevant physiological studies to date and virtually no early observational or other studies of temperamental reactivity per se in children with ADHD, either cross-sectional or longitudinal.

Early Developing, Reactive Mechanisms: II. Reward Response and Attention-Deficit/Hyperactivity Disorder

We noted that reactive processes also include approach processes and that impulse control is also affected by the strength of affective states, such as excited approach to reward and angry response to frustration. In the case of ADHD, theorists have been especially interested in the possibility that impulse control can fail because such *approach* processes (excitement to a reward cue) are either over- or underresponsive to context.

The neural locus of this system is also of interest because it corresponds to neuroimaging findings in ADHD, with an important role for ascending dopaminergic fibers in the brain's appetitive system, known as the mesolimbic dopamine system (Depue & Collins, 1999; Gray, 1971, 1982). These fibers proceed from the substantia nigra and ventral tegmentum to the basal ganglia (especially the caudate nucleus), limbic system, lateral hypothalamus, and prefrontal cortex, thus touching several structures implicated in ADHD and overlapping with the dopaminergic projections thought to modulate executive behavioral control. Note that a related motivational concept, that of *effort*, is discussed in alternative theoretical traditions (Sergeant et al., 1999). We include effort in our broad concept of motivational approach, following Scheres, Oosterlaan, and Sergeant (2001) and Sergeant (2005).

Historically, there was initial interest in the hypothesis of an *overresponsive* approach system in ADHD while also considering the possibility of underresponsivity (Gorenstein & Newman, 1980; Gray, 1991; Haenlein & Caul, 1987; Newman & Wallace, 1993). Experimentally, we would expect that an *overactive* reward system would lead children with ADHD to overrespond in the presence of reward cues, but not when reward cues are absent. It has been difficult, however, to isolate such a context-specific effect

in ADHD (Iaboni et al., 1995; Oosterlaan & Sergeant, 1998a) raising an important obstacle for a straightforward excess-reward-response model. Clarifying this picture, other behavioral findings suggest that ADHD children are overresponsive to recent or immediate reward but underresponsive to more time-distal contingencies (Douglas, 1988; Tripp & Alsop, 1999). Failure to consider temporal properties of the reward could account for the inconsistent results in a number of studies.

As a result, in the past decade, theorists emphasized the temporal properties of the reward as key to understanding impulsivity and ADHD. Children with ADHD are hypothesized to be underresponsive to delayed rewards but normally or even excessively responsive to immediate incentives. This pattern is described as a steepened “delay-reward gradient” because a graph of strength of response by time to reward shows a much steeper curve for ADHD than normal. In other words, the drop-off in performance for individuals with ADHD when rewards are delayed is precipitous (an effect demonstrable in certain animal models of ADHD; Sagvolden et al., 2005). In short, under this hypothesis, abnormal relative weighting of delayed and immediate incentives leads to impulsive behavior. Sagvolden and colleagues, in a well-focused theory derived from animal models, hypothesized that extinction following learning should be impaired if there is a reward dysfunction, because new learning will fail to replace the prior overlearned behavior, an effect seen in their animal model (the spontaneously hypertensive rat).

Their preliminary studies of children appear supportive (Johansen, Aase, Meyer, & Sagvolden, 2002), although more replications are needed and data across a wide range of studies are inconsistent with regard to reinforcement responding in ADHD (Luman et al., 2005). Boosting this theory has been recognition that difficulty tolerating delay may be related to reward dysfunction. Sonuga-Barke and colleagues (2002) found that children with ADHD consistently chose immediate small rewards over delayed larger rewards—although they attributed this to strategic avoidance of delay rather than sensitivity to reward itself. In any event, this tendency is as strong as dysfunctional executive inhibition as a correlate of ADHD symptoms (Nigg, Willcutt, et al., 2005; Solanto et al., 2001).

Summary

In summary, a steepened delay-reward gradient (dramatic drop in performance as rewards become more delayed) appears to be one element in the development of ADHD, particularly its hyperactive-impulsive symptoms, that deserves

close scrutiny. Early development of this process during the infancy and toddler years could shed valuable light on the viability of this view as explanatory for some children with problems in impulse control. It represents an area in which an explicitly developmental focus—from very early childhood through middle childhood and beyond—will be essential for future progress.

Later Developing Deliberate or Executive Control of Impulse and Attention-Deficit/Hyperactivity Disorder

With regard to impulse control, executive processes have among their functions that of suppressing task or goal-irrelevant motor responses. This type of impulse-control process is deliberate or effortful and can occur without substantial fear or anxiety motivating it. It involves a distributed neural system that is conceptually and anatomically closely related to the anterior attention system we featured earlier, including the inferior frontal gyrus and a structure in the subcortical basal ganglia called the caudate (Aron et al., 2003).

Convergence of approaches in describing the executive control system is apparent, given that deliberate or effortful control of responding is emphasized in theories of both early cognitive development (Zelazo et al., 2003) and early social-emotional development (Murray & Kochanska, 2002). However, these approaches have not yet been fully applied to the development of risk for ADHD. For example, surprisingly little research has considered *temperament* antecedents such as effortful control or personality outcomes such as Conscientiousness and Constraint in relation to ADHD (Nigg, Goldsmith, & Sachek, 2004; Olson, 2002; Sanson, Smart, Prior, & Oberklaid, 1993).

Yet, the few studies to do so are quite consistent in suggesting that a broadly defined deliberate control domain (usually studied as Conscientiousness in adults, or as Effortful Control in children) is associated with ADHD symptoms in preschool children (Goldsmith, Lemery, & Essex, 2004), school-age children (Martel & Nigg, 2005), and adults (Nigg, Blaskey, Huang-Pollock, & John, 2002; Nigg, John, et al., 2002). However, unsurprisingly for such a broad, higher-order construct, those findings are nonspecific. That is, many childhood psychopathologies are related to effortful control. However, initial efforts to parse specificity and comorbidity have been promising as well. For example, we showed that Big Five conscientiousness was related to symptoms of inattention-disorganization even with antisocial behaviors partialled; the converse was

not true (Nigg, Blaskey, Huang-Pollock, & John, 2002). Using partial correlations to isolate effects, we also found that in children, effortful control was related to inattention-disorganization, whereas, other traits were related to other disruptive behaviors (Martel & Nigg, 2005). It will be important for future research to consider the key subcomponents of effortful control (Murray & Kochanska, 2002) and of conscientiousness/constraint. In the meantime, of considerable interest are more fractionated measures of strategic impulse control in the laboratory.

Some two dozen different measurement tasks have been claimed to measure behavioral inhibition of the strategic or executive variety (see Nigg, 2000, 2001). However, only a handful come close to isolating the ability to suppress a response, as distinct from attention, working memory, and the like—and even those do not succeed entirely. Perhaps the most theoretically pure measure of the ability to stop an impulse for strategic (rather than affective) reasons is the stop task (Logan, 1994). This task uses varied timing of warnings to evaluate how much time individuals need to interrupt a response they were about to make. Although the task has some psychometric problems (e.g., the variance in stop signal reaction time is unknown), it has performed well in simulation studies (Band, van der Molen, & Logan, 2003). Some 27 studies have used this measure with ADHD and they generally identify a moderate-size weakness in the time needed to stop a response, on the order of $d = .61$ versus normal controls, with over 80% of these studies finding a group effect (Nigg, 1999; Schachar & Logan, 1990; Schachar, Mota, Logan, Tannock, & Klim, 2000; for reviews, see Nigg, 2001; Oosterlaan, Logan, et al., 1998; Willcutt et al., 2005). Thus, this measure of response inhibition is among the most well established correlates of ADHD in the field.

Other measures, such as the oculomotor antisaccade task (Castellanos et al., 2000; Nigg, Butler, Huang-Pollock, & Henderson, 2002) and the go/no go task (Trommer, Hoeppner, & Zecker, 1991; Yong et al., 2000) are also widely viewed as operational measures of strategic response suppression. Such measures also generally show a deficit in children with ADHD versus normal controls, although nonreplications can be noted (see Nigg, 2001, for detailed review). The ability to strategically interrupt or prevent a response may be more strongly associated with behavioral symptoms of inattention than of hyperactivity-impulsivity (Castellanos & Tannock, 2002), converging with personality data, in which trait conscientiousness, the personality proxy for effortful control, was related most clearly to inattention symptoms (Nigg, John, et al., 2002).

Consistent with that picture, in their large study of adults with ADHD, Nigg, Stavro, et al. (2005) used composite measures of inattention-disorganization and hyperactivity-impulsivity (each taken from the subject and two other reporters who completed clinical structured interviews about the subject, validated with a confirmatory factor model fitting analysis) to statistically predict a composite executive function latent variable (based on 5 tasks and also validated with a latent variable confirmatory factor analysis); only inattention symptoms were uniquely related to the executive control score. However, in a logistic regression analysis to predict ADHD subtype with both a composite executive function score and a composite output speed score (as a crude indicator of state regulation or activation), ADHD-C was predicted by executive function weakness but not slow response speed, whereas ADHD-“other” (a compendium of less severe groups, including inattentive, residual, and hyperactive types) was predicted by slow response speed. Thus, partial progress is at hand with regard to specificity of executive deficits to symptom domains by adulthood, but translating this into actual subgroups of individuals with ADHD is as yet incomplete. More work is needed to verify this picture in children, for whom this structure may be less stable.

Impulse Control: Interim Conclusions and Additional Considerations

It is important to recognize that other potential mechanisms in impulse control (and inattention) have received scant discussion here. For example, we noted that the fight-flight response is beginning to receive study. Likewise, because of strong neuroimaging findings of cerebellum abnormality in ADHD (Geidd, Blumenthal, Molloy, & Castellanos, 2001), a long-standing interest in time perception and timing in impulsive adults (see Parker & Bagby, 1997, for a review of early studies) is rapidly expanding into a new body of literature on children as well as adults with ADHD (Barkley, Murphy, & Bush, 2001; Ben-Pazi, Gross-Tsur, Bergmann, & Shalev, et al., 2003; Brown & Vickers, 2004; Sonuga-Barke, Saxton, & Hall, 1998; Toplak, Rucklidge, Hetherington, John, & Tannock, 2003) and may eventually prove quite central to a complete picture of the disorder. Likewise, we have bypassed the literature on serotonergic functioning, a major topic in the literature on impulsive aggression (Coscina, 1997). Finally, the role of language functioning in self-regulation represents a notable omission in our coverage to this point. We say more about it subsequently.

Nonetheless, much has been learned in the past decade as the field has focused heavily on impulse control via inhibition models of ADHD. Three salient if preliminary conclusions can be noted. First, reactive or anxiety-based response suppression (behavioral inhibition) does not appear to be central to ADHD, apart from its linkage to early-onset Conduct Disorder. Second, abnormal reward response, particularly related to temporal properties of reward, shows promise as a potential contributing causal mechanism in at least some cases of ADHD and to the hyperactive-impulsive behavioral symptom domain. Third, measures of strategic or executive response suppression show consistent and moderate-size effects in children with ADHD, albeit clearest and most well-replicated in only a few measurement paradigms (e.g., stop signal task) that still receive some debate as to their properties. These response suppression measures may be related to symptoms of inattention-disorganization as much or more so than to symptoms of hyperactivity-impulsivity. Other executive functions, including control of working memory, also appear to be involved. In all, reward functioning and executive control, perhaps in the form of response suppression, emerge as potential core causal mechanisms in ADHD. Notably, it remains unclear whether difficulty in one of these domains explains the others. For example, increasing reward salience may normalize problems in “stop inhibition” related to ADHD (Konrad, Gauggel, Manz, & Scholl, 2000; Oosterlaan & Sergeant, 1998a; Scheres et al., 2001; Slusarek, Velling, Bunk, & Eggers, 2001), or such “stop inhibition” problems may relate to a failure to alert quickly to the warning cue (Brandeis et al., 1998), but designs to evaluate the contribution of executive dysfunction to motivation or alerting problems are lacking. In all, sorely needed are additional integrative studies that consider multiple neurocognitive domains in the same sample.

As a result, leading theories of ADHD differ in the primacy placed on key processes, with some placing executive functions as the driver of ADHD difficulties (Barkley, 1997; Schachar, Tannock, & Logan, 1993), and others placing reactive or state regulation (arousal, activation, or motivation) processes as the driver of the problems (Sagvolden et al., 2005; Sergeant et al., 1999; Zentall & Zentall, 1983). However, all tend to incorporate to at least some degree executive control, arousal and/or activation, and motivation or reward response. What remains is clarification, both dynamically (i.e., in online behavior response) and developmentally, of how breakdowns in one process may lead to breakdowns in the others, in an effort to clarify whether one process is the predominant driver of

these multiple process dysfunctions in the majority of children with ADHD.

TOWARD A DEVELOPMENTAL, MULTILEVEL PERSPECTIVE ON CONTROL OF ATTENTION AND IMPULSE IN ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Thus far, although we have pointed out the developmental trajectories of key mechanisms implicated in ADHD, we still have treated mechanisms of attention and impulse control in relatively individualistic and static fashion, primarily by considering psychological processes *within the child*. As we noted early on, however, the developmental progression of these within-child processes is highly related to socialization contexts: early parent-family interactions and later peer and school environments. Although this point is well recognized, it is not often reflected in empirical reports. We therefore move to a developmental perspective that enables us to take a multilevel view of the regulation problems under consideration, in keeping with the multilevel approach advocated in developmental psychopathology (Cicchetti & Dawson, 2002). To do so, we emphasize a temperament-based perspective, which enables us to capture in a single framework effortful control, affect/motivation, and arousal, while we also consider a key cognitive domain not yet discussed, language development.

Regarding the last item, we note the following. Language plays an important role in self-regulation as one mechanism by which control is exerted (e.g., by internalized speech; Berk, 1986). It is a key mechanism mediating the socialization of self-control via parental verbalization of affect states and other behavioral expectations (Greenberg et al., 1991). The importance of language in self-regulation for ADHD was a fundamental insight in the influential developmental theory offered by Barkley (1997). However, in our account, we emphasize the putative mutual influence between language and executive function development, which we argue likely parallels the interactive relationship between reactive and executive control processes. The scaffolding of these interrelated control processes in early development can help us understand how disorders of attention and impulse regulation emerge.

As these interrelated, within-child regulatory processes proceed across development, they are collectively entwined in yet another mutual-influence relationship: their interface with the socialization environment. The key consideration in that regard concerns recent clarification that

neural development is plastic to experience (Huttenlocher, 2002) and that experiences support both cognitive and language development (Hollich, Hirsh-Pasek, & Golinkoff, 2000; Posner & Rothbart, 2000). At the same time, just as child social and cognitive development is said to depend on “good enough” caregiving, the socialization process also depends on “good enough” development of executive, reactive, arousal regulation, and language mechanisms in the child. Attention and language are the most obvious points of interface between caregivers or peers and a child’s internal self-control abilities. Over time, the *internalization* of those socialization mechanisms (e.g., in the formation of conscience) is an important yet poorly understood element of the development of self-control. Let us unpack these multiple developmental components in a bit more detail.

Regulatory and Reactive Processes in Development of Self-Control, Revisited

The early development of self-control capacities has been provocative from the viewpoint of considering precursors to attention and impulse control problems. Rothbart and Ahadi (1994) outlined a developmental sequence based on their work with infants, which is similar to several other conceptions in the literature (Block & Block, 1980; Eisenberg et al., 1997; Kochanska et al., 1997; Murray & Kochanska, 2002) and informs our illustration in Table 9.4. This outline is, of course, closely related to our framework of reactive and strategic or executive impulse control mechanisms, a framework that also draws on their work. Using this perspective, we can readily extend our discussion, at a conceptual level, to early precursors (see Sanson et al., 1993).

Early on, infants allocate their attention (and their motor responses) simply on the basis of stimulus response and reflex response, which are largely midbrain-mediated processes that correspond to the reflexive attentional mechanisms discussed earlier. However, by later in infancy, sometime in the 1st year of life, children begin to respond to cues for incentives by directing their attention and making motor responses such as approaching a potential reward or withdrawing from a potentially distressing signal (Rothbart & Ahadi, 1994). These latter responses correspond to the *reactive* allocation of attention and control of behavior that we discussed earlier. By the beginning of the toddler period, roughly about the age of 14 months, infants can be observed to deliberately turn their attention away from upsetting material, exemplifying a precursor to deliberate regulation of behavior and affect by executive control. As discussed much earlier, this process illustrates the concept of effortful control, which (along with the term “regulation”) has emerged in the temperament literature to describe the earliest manifestations of deliberate attention allocation by infants and then toddlers and preschoolers (Rothbart & Bates, 1998).

Effortful control develops rapidly in the toddler years. By about 30 months of age, children can begin to inhibit stimulus-driven motor response (Diamond et al., 1997; Posner & Rothbart, 2000) and thus begin to be evaluated using some of the laboratory measures of attention and impulse control that we reviewed earlier in relation to ADHD findings. For example, by this age, they can engage in interference control, go/no go, and stopping tasks (Diamond et al., 1997). Diamond and colleagues documented a steady development in the ability to inhibit competing, stimulus-driven motor responses by ages 3, 4, and 5 years (see also

TABLE 9.4 Schematic of the Developmental Timing of Different Behavioral Systems Involved in Impulse Control and Attention Regulation

Process	First Emerges in Development	Later Development
1. Reactive approach and inhibition	Infancy (middle of 1st year)	Canalizes or changes with experience in early to middle childhood
2. Effortful/executive control of impulse and attention (anterior attention system)	Toddler (years 1–2) → onward	Matures throughout childhood and adolescence
3. Language	Toddler (years 1–2) → onward	Matures in childhood with growing skill through middle adulthood
4. Posterior attention system	Infancy (1st year)	Matures by early to middle childhood
5. Vigilance/arousal	Infancy (early in 1st year)	Temperament trait responsive to context and caregiving
6. Socialization	Infancy (attachment/attunement)	Internalization of conscience, peer relations in childhood/adolescence

Note: Based in part on “Temperament and the Development of Personality,” by M. K. Rothbart and S. A. Ahadi, 1994, *Journal of Abnormal Psychology*, 103, pp. 55–66. Adapted from “On Inhibition/Disinhibition in Developmental Psychopathology: Views from Cognitive and Personality Psychology and a Working Inhibition Taxonomy,” by J. T. Nigg, 2000, *Psychological Bulletin*, 126, pp. 200–246.

Zelazo et al., 2003). However, Diamond et al. observed subtle difficulties in children with early treated phenylketonuria (PKU). PKU is of interest because this metabolic disease interferes with development of the prefrontal cortex. These results therefore are of note because, unlike frank PKU, which causes mental retardation, the early treated children (i.e., those whose diets are phenylalanine-free) display generally normal-range cognitive development yet often have remaining subtle delays in development of the dopamine-rich neural pathways in the dorsolateral prefrontal cortex that are important to later executive functioning (Diamond et al., 1997). Such early treated PKU cases therefore may serve as one model for the subtle neural injury that may cause executive dysfunction in early development in cases of ADHD.

Effortful control in the form of strategic attentional and impulse control continues to develop throughout childhood, yielding steady progress in the ability to ignore competing stimulus-driven responses over the second- to sixth-grade years (Huang-Pollock, Carr, & Nigg, 2002) and the ability to inhibit primary responses over the period from about ages 5 to 7 and beyond (Carver et al., 2001). The ability to suppress responses continues to develop through adolescence (Bedard et al., 2002), presumably aided by ongoing myelination and pruning of frontal cortical neural networks in conjunction with socialization and learning experiences (Benes, 2001). Table 9.4 summarizes this basic developmental sequence in early childhood. Note that these are the same abilities that we reported earlier are assessed as key weaknesses in children with ADHD, suggesting that children with ADHD are in part characterized by difficulties in this developmental progression.

A further clue with regard to potential pathways to ADHD comes from the insight that reactive and effortful processes likely support and modulate each other in early development (Rothbart & Ahadi, 1994) as well as subsequently. Thus, each process depends on the support of the other for optimal development and for optimal self-regulation (Derryberry & Rothbart, 1997; Derryberry & Tucker, 1994; Rothbart & Bates, 1998). If reactive processes are atypical (e.g., very strong approach tendency), then this imbalance may disrupt development of executive functioning by exceeding the "expectable local environment" for those functions. The reverse can also happen, in that weak executive functioning may result in failure of reactive processes to consolidate.

In turn, as the child matures in the social context, the strength of this two-process self-regulation system is likely to influence the child's capacities to be normally socialized by average expectable parenting and peer environments

(Cicchetti & Lynch, 1995) and achieve adequate socialization adaptively in adverse or suboptimal caregiving environments. The import here is that if a child has very strong reactive processes (e.g., extremely strong negative affect), these may interfere with development of effortful control, in turn further weakening ability to regulate the reactive affects. Conversely, weak effortful control as an early temperamental characteristic could lead to difficulty with affect regulation as part of a two-way mutual influence process. This formulation may help to explain why executive and affective difficulties so often co-occur in children with disruptive behavior problems and ADHD. It also raises the possibility, as yet virtually untested, that certain types of early rearing environments or certain types of traumatic experience may predispose individuals to attentional and inhibitory dysregulation even in the absence of temperamental vulnerability (Kreppner et al., 2001).

At the same time, the arousal and alerting processes we described earlier, which are potentially crucial in ADHD, interact with the effortful and reactive processes under consideration in this discussion. Strong reactive responses (e.g., intense anxiety, excitement, or anger) influence arousal levels (Gray, 1982, 1991), with a cascade of associated physiological responses. If the arousal response is dysfunctional, this will also lead to difficulty in modulating reactive response. Moreover, executive control contributes to regulation of arousal, and optimal arousal is likely necessary for effective effortful control (Barkley, 1997; Rothbart et al., 1994).

Therefore, as we consider the development of attention, arousal regulation, reactive processes such as reward responsivity, and executive or effortful control, we can see that in the case of ADHD, there is potential for linking the various laboratory findings with early temperament models. These may be integrated in developmental analyses that identify temperaments at risk if not in infancy (where it is limited by the fact that very early temperament measures typically do not show reliable cross-time stability coefficients) then perhaps in the toddler years, and then measure this risk with laboratory measures in the middle childhood years, as they are consolidating. Thus, the field has the potential, at present, to begin to map early risk pathways toward childhood ADHD if temperamental precursors can be identified and show some stability in instances in which ADHD emerges. In other words, those early risk pathways may be mediated by early temperamental risks, which then mature into primary difficulties in some combination of arousal, approach, and executive impulse control abilities. Crucially, all of these systems are bound to be responsive to socialization contexts and

experiences. We return to these ideas shortly after considering language functions.

Language and Regulatory Processes in Development of Self-Control

We alluded to the need to consider language development to understand self-regulation. The importance of verbal processes such as internalized speech for the development of self-regulation (i.e., executive control) has been well described (Barkley, 1997; Berk, 1986). Yet a mutual influence process is also potentially salient here, although it remains speculative. That is, toddlers typically transition from babbling to interpersonal word usage at about 10 to 14 months of age (Woodward & Markman, 1998). Language development then proceeds rapidly during the 2nd through 4th years of life. Of particular importance, this timing converges with the coming online of deliberate control mechanisms described earlier. This is probably no coincidence, as language learning is highly likely to be facilitated by attentional control (the youngster's ability to attend to caregivers when language or vocabulary teaching is going on; R. Brand & D. Baldwin, personal communication, August, 2005; Hollich et al., 2000). In short, children learn what they attend to. Because attentional control may be unduly influenced by reactive as well as arousal processes in a child with delayed development of effortful control, language learning may be delayed or altered by these attentional determinants during the toddler years in some children. For example, to enable language to advance rapidly, the child must be able to look away from stimulus-driven attentional targets and toward strategic targets cued by caregivers (Bloom & Tinker, 2001). In all, verbal facility, vocabulary, and general language effectiveness may be supported by the involvement of emerging effortful control of attention in the 2nd through 4th years of life.

Such advances in language are then theorized to support further strengthening of executive control in a bootstrapping manner, for example, via internalized speech and self-talk (Barkley, 1997). Verbal learning problems are a frequently identified correlate of antisocial development (T. E. Moffitt, 1993). However, verbal learning and language problems are not typically emphasized in the etiology of ADHD, even though they are frequent correlates (Barkley, 1997; Tannock & Schachar, 1996) and may well deserve more scrutiny (Tannock & Schachar, 1996). Indeed, Baker and Cantwell (1992) found that a high percentage of children with ADHD during the grade school years had histories of language problems earlier in development (i.e., during the preschool period). Although some of these

problems may have been subtle (e.g., mild dysarticulation), others involved more fundamental receptive or expressive language problems. Note that the mechanism of risk for ADHD could be direct in such instances: Poor language development may delay the ability to regulate behavior via self-talk strategies. It may also be indirect, in that caregivers may become frustrated while interacting with children who do not readily comprehend what is asked of them or who are not themselves easy to understand. Hence, socialization mechanisms may well be an indirect pathway through which developmental language problems contribute to the genesis of ADHD.

In summary, several core processes operate synergistically in early development to provide the child with adequate self-control: reactive processes (including behavioral inhibition and approach directly influencing arousal regulation), effortful control or executive functions, and language. In turn, these within-child self-control processes interact dynamically with socialization in infancy, pre-school, and the school-age years. Figure 9.1 illustrates schematically several of the self-regulation mechanisms

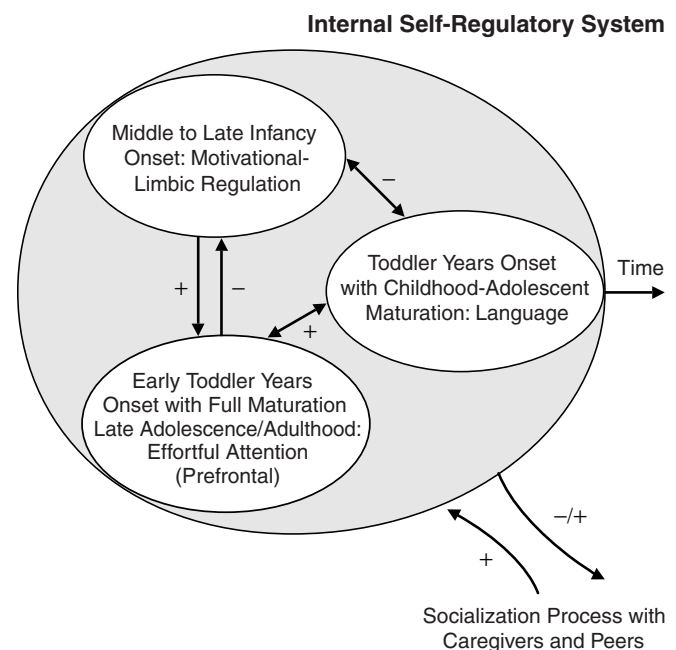

Figure 9.1 Schematic illustration of the within-child processes related to self-regulation and their collective interrelation with socialization effects. Adapted from "An Early Onset Model of the Role of Executive Functions and Intelligence in Conduct Disorder/Delinquency" (pp. 227–253), by J. T. Nigg & C. L. Huang-Pollock, 2003, in *The Causes of Conduct Disorder and Serious Juvenile Delinquency*, B. B. Lahey, T. Moffitt, & A. Caspi (Eds.), New York: Guilford Press.

we have discussed, indicating their interrelations and developmental phasing.

Interpersonal and Socialization Influences in the Development of Self-Control

The child's developmental status with regard to self-control interacts with socialization in a bidirectional and even transactional manner. Thus, children's reactive, control, and language processes depend for their development on adequate social interactions. We note again, in this regard, the notion of the "average expectable environment" necessary for the child's genotype to be expressed and his or her temperament to emerge adaptively (Cicchetti & Lynch, 1995). At the same time, the child's own abilities influence his or her preparedness to internalize social norms (e.g., internalized self-control, later conscience) and, at the same time, provide interpersonal stimuli that shape the responses of interaction partners (parents, peers). In other words, the child's proclivities and tendencies in the domains of attentional control and impulse regulation both shape and are shaped by the interpersonal context in which he or she develops. Thus, we view gene-environment correlations and gene-environment interactions as essential factors related to the development of attention and impulse control (Rutter & Silberg, 2002). Note that the developmental processes we outline here are also relevant to impulsivity as expressed in antisocial behavior (Nigg & Huang-Pollock, 2003, provide a similar analysis, e.g., in relation to antisocial development, which is closely related to ADHD; see Hinshaw, 1987; Hinshaw & Lee, 2003). We point out, however, that different elements and processes in the self-control system may contribute to different manifestations of externalizing psychopathology (Nigg, 2003), allowing some clear distinctions to be made despite the overlap of attention and impulse control problems with antisocial behaviors (see Waschbusch, 2002).

Again, child characteristics can interfere with socialization and make it more difficult for the child to be taught social rules (Johnston & Mash, 2001). This difficulty can lead, for example, to breakdowns in the normal development of conscience (Kochanska et al., 1997), particularly if the rearing environment is not well attuned to the child's needs (Greenberg et al., 1991). Also possible, but less well supported empirically, is that subtle or greater failures in normal socialization (short of frank trauma), such as parental psychopathology, preoccupation, impulsivity, or conflict, may directly impede the child's development of internalized self-regulation (Johnston & Mash, 2001). A

recursive loop then can develop in which the child inadvertently contributes to negative socialization experiences (Hughes, White, Sharpen, & Dunn, 2000) and vice versa. The preschool years are an especially critical time for these socialization dynamics, as language, deliberate effortful control, and affect regulation develop rapidly via interpersonal relations with caregivers. Various kinds of family stressors therefore may be related to inattention and impulse-related ADHD symptoms, perhaps because they disrupt the ability of caregivers to participate fully in this developmental dialectic. In turn, various characteristics of caregivers—including emotional dysregulation, disorganization, anger, and hostile interchanges with partners—can influence children's attention and behavior through genetic mediation of both parental and child characteristics (note, in this regard, the moderate to strong heritability of ADHD-related symptoms), through direct socialization influences, and through temperamental elicitation of particular caregiver responses. In short, an array of direct genetic linkages, direct psychosocial influences, and correlated genetic/biological and psychosocial risks are all likely to play a role in the transactional patterns that develop (Hinshaw, 1999, 2002a).

At times, this disruption may be driven by the difficulty of the child's behavior, limitations of the child's effortful control of attention, or intensity of child's affective reactions. The last would represent cases in which the child's characteristics (which, as we have just noted, are likely to be genetically influenced) lead to later ADHD, through both the continuity of the underlying temperamental characteristics and the mediating and accentuating mechanisms of disrupted parent responses (Rutter & Silberg, 2002; Scarr & McCartney, 1983). In other instances, as suggested earlier, it may be that marked disruptions in rearing environments are the key causal variable. Most likely is the possibility of transactional, reciprocally deterministic pathways.

At this point, we briefly review what *is* known about how socialization influences the development of ADHD as well as the types of aggressive and disruptive behavior that frequently accompany this condition. First of all, we highlight that most commentators contend that parenting and socialization are largely unrelated to the early display of disrupted attentional processes and impulse control problems (e.g., Barkley, 1998; Hinshaw, 1994) because of at least two factors: (1) As was discussed earlier, the symptoms of ADHD show strong levels of heritability throughout development (Hay, Bennett, McStephen, Rooney, & Levy, 2004), along with almost zero levels of shared environmental contributions; (2) there is no evidence for any

association between disruptions in attachment status and subsequent ADHD patterns in the child (Hinshaw, 1999). On the other hand, insecure attachment between caregiver and child is a common correlate of frankly aggressive behavior in children, providing at least preliminary evidence for the contention that early problems in bonding between children and parents are related far more specifically to disruptive and antisocial behavior than to attention and impulse control problems *per se* (Greenberg et al., 2001).

Second, however, isolated reports indicate a potential linkage between early disruptions in parent-child relationships and later ADHD. One group (E. A. Carlson et al., 1995; Jacobvitz & Sroufe, 1989) provided evidence that, in a low-socioeconomic sample, early maternal misattunement to the child's cues predicts ADHD-related symptomatology several years later. A related study suggested that hostility between family members in the toddler years predicted ADHD symptoms in grade school in a small sample of non-diagnosed children, although toddler levels of behavior problems were not controlled (Jacobvitz, Hazen, Curran, & Hitchens, 2004). Perhaps consistent with those findings, Jester et al. (2005) followed a large sample of at-risk children from preschool to adolescence, examining the family and parenting predictors of four trajectories of development of attention problems (by the Child Behavior Checklist and Teacher Report Form attention problems scale, which includes hyperactivity items) and aggression. Lower emotional support and lower intellectual stimulation by the parents in early childhood predicted membership in the most problematic inattention trajectory, even when the trajectory for aggression was held constant. Conversely, conflict and lack of cohesiveness in the family environment predicted membership in a worse developmental trajectory of aggressive behavior with inattention/hyperactivity trajectories held constant. Those findings provide some of the first evidence for the potential specific contribution of distinct parenting or home experiences to ADHD spectrum and aggressive behaviors. Despite these intriguing reports, however, in the absence of a genetically informative design, it is unknown whether these instances of possible psychosocial mediation are, in fact, related more specifically to shared genetic characteristics between mother and offspring. Although Jester et al. did covary parental ADHD status with no change in results, most family studies failed to control parent ADHD. Thus, nearly all research on socialization influences across developmental psychopathology suffers from the key problem that genetic and psychosocial mediation of parenting or family life are confounded when biological parents and children are investigated (Rutter, Pickles, Murray, & Eaves, 2001). The types of adoption or twin de-

signs designed to isolate the separate and interactive contributions of genes and environmental/socialization influences as related to the development of attention and impulse dyscontrol have simply not been performed.

Third, the predominant perspective over the past 25 years or so has been that associations between negative parenting or disrupted socialization on the one hand, and ADHD symptomatology on the other are the product of child effects on caregivers, rather than the predominant view during the middle of the twentieth century that socialization was clearly the causal route for nearly all child behavioral disturbance (see Bell, 1968). The classic investigation of Barkley and Cunningham (1979) was paradigmatic in this regard: When hyperactive children were switched from placebo to medicated status, the negative/controlling maternal behaviors observed during objectively coded interactions were dramatically reduced. (Note, however, that positive parenting behaviors did not yield such a clear, reciprocal increase as a function of child medication status.) Such work has prompted the predominant view that parenting styles are a reaction to, rather than a contributor to, ADHD-related noncompliance and oppositionality.

Fourth, however, such studies of the acute effects of stimulant medication in yielding reciprocal reductions of parental negativity do not speak to the longer-term, interactive influences between temperament and socialization in shaping ADHD-related symptomatology. That is, there may be a history of negative interaction patterns—spurred initially by parental difficulties in reacting to difficult temperamental styles in the child—that propel intensification of attentional and impulse control problems. Along this line, we highlight at the outset that clear experimental evidence exists regarding the decisive role of negative parenting practices in shaping and maintaining aggressive and externalizing behavior patterns in children (G. R. Patterson, Reid, & Dishion, 1998; Snyder, Reid, & Patterson, 2003). In other words, interventions designed to test parent management programs aimed toward reduction of aggressive behavior indicate that the interventions are effective and improvements in parental discipline practices mediate such outcomes. Furthermore, as noted, severe disruptions in early caregiving may have specific effects on attentional and impulse control (Kreppner et al., 2001).

With regard to research evidence for the influence of parenting factors on ADHD and associated symptomatology, cross-sectional research utilizing ample statistical controls has demonstrated that, among boys with ADHD age 6 to 12 years, maternal negativity predicts rates of stealing and noncompliance even when the child's negative and noncompliant behavior with the mother is partialled

(Anderson, Hinshaw, & Simmel, 1994), and authoritative parenting beliefs (emphasizing warmth, clear limit setting, and a push toward autonomy) predict social competence for these boys (but not comparison boys), even with control of the child's behavior patterns in the peer group (Hinshaw, Zupan, Simmel, Nigg, & Melnick, 1997). Thus, parenting appears to make an independent contribution to antisocial behavior patterns and peer relationships in boys with ADHD, albeit not to the symptoms of the disorder *per se*.

Furthermore, longitudinal research demonstrates that parenting style and parenting practices predict the maintenance of ADHD-related symptomatology across the preschool years into middle childhood (Campbell, 2002), even with initial rates of hyperactivity and impulsivity controlled. As for experimental evidence, Hinshaw et al. (2000) examined the effects of self-reported parenting practices on child outcome in the context of a large, randomized clinical trial for children with ADHD that featured the treatments of stimulant medication, intensive behavior therapy, and the combination of the two (MTA Cooperative Group, 1999). The crucial finding was that, as hypothesized, reductions in negative/ineffective discipline practices mediated large increases in teacher-reported social skills and were associated with the full normalization of teacher-reported disruptive behavior across the 14-month period of active intervention. That is, children receiving the multimodal treatment featuring carefully monitored medication plus consistent behavior management training whose parents reported the strongest improvements in their negative/ineffective discipline were those whose school behavior had normalized across the treatment period. Thus, even for a condition as heritable as ADHD, changes in parental discipline style during middle childhood are associated with, and explain statistically, school-based improvements in social skills and disruptive behavior.

Still unknown are the following: At the level of specifically and formally defined attentional and impulse control mechanisms, how do parenting and other forms of socialization interact with child temperament and the within-child mechanisms discussed earlier to shape the development of self-control? Do wider community and systems influences, perhaps even including the extreme societal press for earlier and earlier display of academic excellence and the barrage of media influences via television and computers, propel the enhancement (or, in some cases, the diminution) of attentional mechanisms in the developing child? How salient are sex differences (see Blachman & Hinshaw, 2002; Gaub & Carlson, 1997; A. Moffitt, Caspi, Rutter, & Silva, 2001; Nigg, Blaskey, Huang-Pollock, & Rappley, 2002) and cultural/ethnic differences (Mueller et al., 1995) in this re-

gard? Unfortunately, hardly any sound data exist with regard to these putative triggers and moderator mechanisms. We do note, however, that ADHD is not a phenomenon solely displayed in the United States or even Western nations; its manifestations and impairments appear to be cross-cultural, at least to some extent (Barkley, 2006; Hinshaw & Park, 1999). Sorely needed are ambitious research programs that include genetically informative designs, which can tease apart genetic and environmental (and interactive) influences on the development of attention and impulse control; longitudinal follow-ups of children in such investigations; and prevention and intervention studies designed to help address putative risk and causal mechanisms (Hinshaw, 2002a).

Summary

We highlighted that the development of self-control is dynamic within the child: Reactive, executive, and language processes mutually influence one another to enable the regulation of attention, arousal, and impulse control. In turn, the child's capabilities influence the socialization environment and vice versa. Interactive and transactional processes (still poorly understood) are thus likely to be the rule rather than the exception for the development of attention and impulse dysregulation. In all, considerable etiological heterogeneity is likely in the pathways to problematic inattention and impulse control. In other words, it is quite possible for some children to exhibit poor self-control due largely or exclusively to contextual problems; for others to exhibit similar problems due to within-child weaknesses in self-control via reactive, executive, or other intraindividual processes; and for many (if not most) to reveal a complex blending of these causal paths.

HETEROGENEITY AND MULTIPLE DEVELOPMENTAL PATHWAYS

Following our last point, most reviewers of the ADHD literature now explicitly note that multiple causal pathways are highly likely to be involved in the development of the many children identified as having ADHD, exemplifying equifinality and, more often, multifinality in system process (Cicchetti & Rogosch, 1996). Yet, as we consider how to construct even better theories of ADHD for the twenty-first century, one of the most striking limitations in theories of this condition until the past decade was that they often did not formally address the likelihood of such multiple causal pathways, or etiological heterogeneity (Taylor,

1999). Heterogeneity is obvious at the clinical level. Children with impulse control or attention problems vary widely with regard to the associated behavioral and emotional problems they display. Recall, for instance, the high rates of various clinical comorbidities associated with ADHD, with some children exhibiting comorbid anxiety, others antisocial behavior and conduct problems, others learning disabilities, and some showing problems in all such domains.

The importance of heterogeneity is also evident from examining the distributional properties of test scores in mechanism-based studies of clinical samples. The typical overlap of, for example, executive functioning scores between ADHD and control children is on the order of 50% or less (Nigg, Willcutt, Doyle, & Sonuga-Barke, 2005; Swanson et al., 2000). As a result, sensitivity and specificity of cognitive measures to ADHD remains notoriously poor (Fischer, Newby, & Gordon, 1995; Grodzinsky & Barkley, 1999). Although this overlap may indicate variation in two homogeneous populations, the point that half of children with ADHD have normal-range results on any particular cognitive, neural, or physiological measure (including neuroimaging measures) could also suggest that some proportion of children diagnosed with ADHD in terms of the current behaviorally based criteria do not have an internal dysfunction that would be associated with a formally defined disorder (Wakefield, 1992). Such neuropsychological or genetic heterogeneity almost surely exists *within* the present *DSM-IV* subtypes. Thus, based on their findings of neuropsychological weakness in one group and dopamine gene dysfunction in another group, Swanson et al. suggested that one group of children with ADHD has a genetically influenced temperamental disposition, and the other has neuropsychological deficits with a different etiology, perhaps as a function of perinatal neural injury or other genes. Additionally, Nigg, Blaskey, Stawicki, and Sachek (2004) divided children with ADHD into “normal” and “impaired” (defined as worse than the 90th percentile) on a series of executive function tasks. They observed that relatives of the EF-impaired children had weaker neuropsychological performance than relatives of the non-EF-impaired ADHD children. Furthermore, relatives of non-EF-impaired ADHD children performed similarly to relatives of non-ADHD control children. Those data provide some initial support for the validity of a subgroup of children with ADHD who have executive function weaknesses. Biederman et al. (2004) conducted a similar analysis looking at academic impairment and noted that children with ADHD with poor executive functioning had more impairment than other children with ADHD. In line with these types of data,

Sonuga-Barke (2002) suggested that two developmental pathways may be disturbed, one driven by within-child neuropsychological difficulties with executive functioning, the other by a mismatch between temperament and socialization, leading to a resultant breakdown in reward regulation and motivation.

Heterogeneity is also apparent within the ADHD-I type. Recent work suggests the potential importance of differentiating children with sluggish, hypoactive style from those with normal or above-normal activity level (C. Carlson & Mann, 2002; McBurnett et al., 2001). EEG studies have begun to examine individual differences in children with ADHD using cluster analytic and related techniques. At least some concluded that ADHD-C is, in fact, heterogeneous, including a group with a high theta-beta ratio, interpreted as CNS *hypoarousal*, and a smaller group with excess beta activity, interpreted as CNS *hyperarousal* (Chabot & Serfontein, 1996; Clarke, Barry, McCarthy, & Selikowitz, 2001a, 2001b). Again, such evidence suggests strongly that children within a given *DSM-IV* subtype are not etiologically homogeneous.

Aside from the possibility that different causal mechanisms may lead to the same ADHD phenotype—exemplifying equifinality but therefore complicating etiological research as well as the quest for definitions of which children are most appropriately viewed as displaying a true clinical disorder—another multiple-pathway possibility exists. That is, the multiple co-occurring problems in ADHD (e.g., language problems, motor control problems) could reflect multiple causal processes rather than one core process operating *within* each child. For example, Sagvolden and colleagues (2005) suggest that disruption in dopaminergic systems leads to (1) breakdown in basic reward response in one dopamine pathway, the mesolimbic pathway, resulting in impulsivity, and (2) breakdown in a basic motor control pathway, the nigrostriatal pathway, leading to hyperactivity. Beauchaine (2001) advises consideration of motivational plus autonomic systems in concert. As noted earlier, Nigg, Stavro, et al. (2005) reported that executive function weakness was associated with inattention-disorganization, and response speed with hyperactivity-impulsivity.

These types of models are an important step forward in theoretical perspectives. However, they do not explicitly address the questions of when and how during development the particular functional breakdowns may occur, or how they are maintained over time in some cases and improve in other cases. Therefore, a next step in such models is to suggest alternative *developmental* sequences, timing, or influences with respect to multiple pathways. To illustrate, we can again borrow from the dialectic logic described earlier,

which draws on the work of Rothbart and colleagues (Rothbart & Ahadi, 1994; Rothbart & Bates, 1998). If we draw out the implications of that model for ADHD and its comorbid expressions, we can suggest alternative routes with diverse “primary dysfunctions” (see Nigg, Goldsmith, et al., 2004).

For example, considering again Table 9.4 and Figure 9.1, we speculate that ADHD could develop in some children due to a breakdown in early effortful control processes, perhaps related to early abnormalities of neural development or, alternatively, to temperament or temperament-socialization dynamics beginning in the toddler years. Still lacking is specification of the precise types of socialization influences that are crucial—although harsh, emotionally dysregulated, and inconsistent parenting would be a prime suspect. Other children may develop ADHD symptoms as a result of excessive or unusual reactive processes (e.g., strong approach tendencies), perhaps evident as early as infancy but also dependent on breakdowns or at least suboptimal socialization and attunement by caregivers. Some may have very strong inborn traits that overwhelm socialization efforts, whereas others may reflect difficulty adapting to insufficient or unresponsive social contexts. In any case, it is doubtful that all children with ADHD will exhibit, executive function problems, reinforcement-response problems, or any other single neuro-cognitive dysfunction. Rather, such claims will be applicable only to an as yet unspecified subset of children to whom the diagnostic label is currently assigned.

Speculations and even data exist on complex, across-time relationships that may be pertinent to such contentions. For example, G. E. Patterson, diGormo, and Knutson (2001) contend that ADHD is a precursor to antisocial behavior in a pertinent subset of children, consistent with the relative rarity of finding clinical levels of conduct problems and antisocial behavior in children who are not impulsive and hyperactive. Of course, heterogeneity exists in the developmental trajectories leading to antisocial outcomes, in that one route appears to be a lifelong path beginning with temperamental problems, early manifestations of ADHD and verbal processing deficits, and increasingly conflictual family interactions, whereas another, less pathological trajectory begins during adolescence without the same psychopathological precursors in childhood (T. E. Moffitt, 1993). As highlighted earlier, clearly needed are the kinds of research designs that can incorporate the potential for uncovering disparate developmental trajectories, that feature measurement of basic attention and impulse-related processes as well as behavioral indicators of dysfunction, and that pay careful attention to socialization influences as

well. In all, more formal definitions of multiple pathways to ADHD and its subtypes are needed to guide the next generation of etiological research.

FUTURE DIRECTIONS AND CONCLUSIONS

As should be apparent from this review, no single mechanism or perspective will be sufficient to explain the phenomenon of disorders of attention and self-regulation in children. We have highlighted that along with a handful of key cognitive functions (executive control of attention and response suppression, reward response, and state regulation implicating arousal or activation functions), socialization contexts are important mediators of problem development. We have also called for deeper analysis and theorizing of developmental processes (rather than static “dysfunctional mechanisms”) in children with these disorders. Finally, we have emphasized the importance of more formal consideration of heterogeneity in empirical and theoretical efforts. Before we conclude, we note several key questions confronting the field at this juncture. Progress in the coming decade may well depend on the answers to these questions. We largely bypass the important domains of continued work on behavioral and molecular genetics, neuroimaging, and pharmacology related to ADHD (see Levy & Hay, 2001; Solanto, Arnsten, & Castellanos, 2001; Swanson & Castellanos, 2002), because those domains are currently well recognized as important in the field. Instead, we highlight issues that may be less well appreciated at present.

First, as we intimated, progress is likely to be limited until more explicit parsing of heterogeneity in neuropsychological, genetic, and other etiological approaches is accomplished. Until then, small effect sizes and inconsistent replication (often using underpowered samples) are likely to sow confusion among scientists and foster continued disputes about ADHD as a disorder. Molecular genetic approaches may be of help here (Swanson et al., 2000), but they will not be sufficient by themselves. Absolutely required are more sophisticated statistical efforts to uncover subgroups related to cognitive profiles in the effort to evaluate whether children with normal versus extreme cognitive dysfunctions (e.g., in executive control of response, arousal, reward response, or related domains) can be reliably and stably distinguished over time. Currently, such children are lumped together in most cross-sectional studies; indeed, the degree to which they can be distinguished post hoc is unexamined. At a more general level, this point underscores the contention that the current subtyping scheme related to

ADHD is highly descriptive and almost certainly quite preliminary—a warning against premature reification of the existing construct.

Second, longitudinal investigations of toddlers and preschoolers may be quite productive in better identifying sequences of developmental breakdown of competing internal regulation systems. That is, investigators need to begin their longitudinal studies earlier in life than they typically do (for a parallel argument related to the need for studies of antisocial behavior to begin in infancy or even prenatally, see Tremblay, 2000). For example, do we observe that children with early effortful control weaknesses are protected from ADHD if they have strong language learning and language socialization? Is it the case that children with poor reward response are protected in the face of executive function strengths? Or is it generally true that a breakdown in one system is enough to pull a child away from adaptive development? Furthermore, can strong family ties or clear, consistent discipline patterns serve to buffer deficits in these areas?

Third, it is essential that we better clarify the contextual moderators of expression of problems in children with ADHD (Johnston & Mash, 2001). Generally, it is observed that extreme scores on neuropsychological tasks are observed in very few well-adapted children but in about half of poorly adjusted children with attention deficits and impulsivity. What are the contextual and family correlates of those few poor scores in the well-adjusted children, and of those many normal scores in the poorly adjusted children? More generally, multilevel studies that consider simultaneously family context and neuropsychological (and/or genetic) correlates are sorely needed. Single-level-of-analysis investigations are still typical and can still inform the field, yet the coming decade should witness greater reliance on investigations that can parse the inherent complexity of disorders of attention and impulse control.

Fourth, whereas much research has emphasized the important domain of *mechanisms*, we have insufficient understanding of *etiology*, especially concerning factors that may influence a whole population (rather than factors that contribute to individual differences; Nigg, 2006). Indeed, it is not even clear whether we are currently experiencing a secular trend of increasing child ADHD problems (see Achenbach, Dumenci, & Rescorla, 2002; Achenbach & Howell, 1993), and more data are needed to clarify matters. If there is such a trend, what accounts for such effects? Potential specific etiologies have not gone far beyond perinatal problems, common teratogens such as smoking and alcohol use, the recognition that increased survival of children born at low birthweight may contribute to a subset of cases (Bres-

lau & Chilcoat, 2000), and the most obvious postnatal toxic exposures (i.e., extensive lead poisoning; Barkley, 2002). Deeper questioning of such etiological risks is warranted. For example, as we speculated earlier, media influences on early neural development remain poorly understood in light of the now intensive exposure of many American youngsters to video and electronic games at very early ages (Anderson & Bushman, 2001). With regard to neurotoxins, low-level (“acceptable”) lead exposures are increasingly being questioned and may remain a contributing problem on a larger scale than previously thought (Bernard, 2003; Canfield et al., 2003). As another example, the influence on behavior of other and more pervasive environmental neurotoxins than lead, notably polychlorinated biphenyls and related compounds that likely affect dopamine systems, is virtually unstudied despite concerning initial findings about the effects of ubiquitous, background-level exposures in both humans (Jacobson & Jacobson, 1996; Korrick, 2001) and animals (Holena, Nafstad, Skaare, & Sagvolden, 1998; Rice, 1999). It is noteworthy that Rice (see also Rice & Hayward, 1997) exposed infant monkeys to low levels of PCBs comparable to background exposures undergone by the average American child. In adolescence, those monkeys had greater impairments in working memory than monkeys receiving no PCB exposure. Thus, more scrutiny of the role of these contaminants in human attention problems is warranted. Finally, and perhaps more speculatively, after initial excessive claims about food additives and then sugar were largely disproven (Conners, 1980; Milich, Wolraich, & Lindgren, 1986), more recent suggestions for ubiquitous dietary effects may still warrant investigation (Richardson & Ross, 2000). Animal models as well as human epidemiological and experimental studies will be clarifying in all these domains.

Most important, however, is greater attention to the potential for gene-by-environment interplay, in which these ecological or environmental risks may have small “main effects” but large effects on segments of the population (i.e., those with a particular genotype; see Rutter & Silberg, 2002 for general overview; see Nigg, 2005 for an overview in relation to ADHD, and Nigg, 2006 for detailed discussion in relation to ADHD). Such interplay is now replicated in relation to antisocial behavior (see incisive discussion by Moffitt, 2005). Identification of the relevant environmental triggers for a particular disorder is key to this strategy. For ADHD, those just mentioned here appear worthy of study in conjunction with molecular genetic designs.

Finally, it needs to be acknowledged bluntly that the field has a woefully inadequate understanding of cultural variation in the mechanisms of attention and impulse con-

trol problems (Hinshaw & Park, 1999). How universal are the mechanisms cited herein? How is their expression different in different ethnic groups in the United States, as well as in different nations and subcultures? In the United States, for example, there is little work investigating the determinants or expression of ADHD in African American or Latino populations or on developmental processes particular to those groups, despite isolated reports that ethnicity and culture can sharply affect behavioral ratings and other evaluations of children (e.g., Mueller et al., 1995). Furthermore, far more is known about ADHD in boys than in girls (Gaub & Carlson, 1997), despite a growing database on female manifestations of this condition (e.g., Hinshaw, 2002c; Hinshaw et al., 2002; Levy, Hay, Bennet, & McStephen, 2005).

The long-term goal of prevention and amelioration of these disruptive problems in children's development, in a manner that enhances child competence and not merely social control, will depend on cogent answers to these overarching questions. Arguably, the field is well on its way. It is characterized at present by a high degree of optimism related to ongoing insights from molecular genetics and neuroimaging. Those insights will continue to be essential for a complete picture of the phenomenon. Moreover, as we identify neuropsychological problems in a subset of children, the validity of ADHD and its status as a formal disease entity will be greatly enhanced (Barkley, 2002). We expect that the definition of ADHD will continue to evolve and sharpen along the way as well.

Nonetheless, multilevel integration will be vital for the field to reach a more powerful level of understanding. The past decade has seen remarkable developments in the sophistication of mechanism-based theories of ADHD (e.g., Barkley, 1997; Douglas, 1999; Sagvolden et al., 2005; Sergeant et al., 1999). The challenge for the next decade (indeed, decades) is to continue to articulate multipathway models (see Berger & Posner, 2002; Nigg, 2006; Nigg, Goldsmith, et al., 2004; Sagvolden et al., 2005; Sonuga-Barke, 2005) and conceptualizations that integrate multiple levels of analysis, including genetic, neuropsychological, and contextual factors. The latter have scarcely emerged; indeed, such studies are daunting in terms of conceptual complexity as well as methodological difficulty and cost. One partial solution may be to embed experimental substudies into randomly selected (or intentionally enriched) subsamples of large, population-based investigations. Another partial solution is to use molecular genetic designs to examine environmental effects in relation to genotype. In the end, the conceptual challenges, clinical realities, and developmental conundrums posed by children with disorders of impulse

and attention make the kinds of multilevel efforts we advocate here extremely worthwhile.

REFERENCES	428

In this chapter, we consider Obsessive-Compulsive Disorder (OCD) from developmental and evolutionary perspectives. We begin with a definition of obsessions and compulsions and a description of this diagnostic category. We then examine several normal epochs of develop-

This work was supported in part by NIH grants MH44843, MH49351, HD03008, RR00125, and RR06022 (General Clinical Research Centers) and grants from the Institute for Research on Unlimited Love. Portions of this chapter have appeared in earlier publications, including Leckman and Mayes (1998, 1999); Leckman et al. (1999); A. Carter, Leckman, and Pauls (1995); Evans (2000); Evans et al. (2004; especially the section on neural circuitry); and Schultz et al. (1999).

ment that are characterized by obsessive-compulsive behaviors that resemble those encountered in OCD. Next, we take a closer look at the phenomenology and natural history of OCD before reviewing the available genetic, epigenetic, neuropsychological, neurochemical, neuroendocrine, and neuroimaging data that bear on OCD and related normal phenotypes. We then detail a number of theoretical models of pathogenesis and the treatments they have engendered. Finally, we offer an integrative model that emphasizes evolutionary and developmental perspectives and describe its potential utility in providing a coherent, multidisciplinary framework for future work in this area.

DEFINITIONS AND CLINICAL DESCRIPTIONS

In the following section we define obsessions and compulsions, and we describe the clinical presentations associated with each construct. In so doing, we hope to emphasize the broad range of behaviors associated with both obsessions and compulsions.

Obsessional Thoughts

Obsessions are intrusive thoughts, impulses, or images that are troubling and persistent and that may dominate the mental life of the individual afflicted (American Psychiatric Association, 2000). Patients often view these pre-occupations as being senseless and bizarre. Obsessions are typically regarded as being ego dystonic, in that they are distressing and contrary to the individual's view of himself or herself. For example, a patient may have intrusive thoughts of having been responsible for harm befalling a close family member, or fear that a loved one will be harmed because of some inadvertent act. Similarly, a new parent may suddenly experience an urge to harm or even kill her precious infant, or a pious individual may be plagued by the obsessive urge to desecrate a holy statue. Typically, the individual is aware that he or she will not act on these troubling impulses, but that does little to diminish the distress that the thoughts engender. Another relatively common obsession involves excessive worries about germs or contracting a fatal disease. Some individuals with OCD are painfully preoccupied with the idea that they may have left a stove on or a door unlocked. Still other obsessions focus on a need for symmetry or exactness or concerns about not discarding things that most people would regard as useless.

Although many of us may have experienced similar thoughts, we are generally able to dismiss them. For individuals with OCD, however, their intrusive thoughts, once initiated, are tenacious and nearly impossible to dismiss. Even in the face of evidence to the contrary, the individual with OCD is often unable to interrupt the flow of these disturbing images and thoughts.

Compulsions

Compulsions include a broad array of repetitive behaviors that a person feels driven to perform, often according to a strict set of rules that must be rigidly applied. The range of compulsions is vast and may include repetitive and excessive hand washing, checking behaviors (checking doors, stoves, or whether a parent is okay), elaborate routines or

rituals surrounding bedtime (dressing or undressing in a certain order or manner, such as left side of the body first) or mealtime (eating foods in a certain order, or avoiding foods of a particular color or texture), or bizarre routines involving movements such as touching or tapping upon crossing a threshold, or "evening-up" behaviors. Some individuals with OCD have strong preferences for symmetry, balance, or wholeness that "requires" that they arrange particular objects in a certain order. Still other compulsions may include repeatedly asking questions or seeking reassurance, or mental rituals such as repeating certain words or phrases to oneself, or needing to repeatedly count to a particular number.

Whereas some compulsions involve elaborate and observable routines or rituals, others are more covert and internal, though even some elaborate rituals may be performed only in private and remain unknown to others. The perceived senselessness of compulsions may bring about psychological distress, yet it is also the case that compulsions may bring temporary relief from anxiety. That is, hand washing temporarily relieves the anxiety from contamination obsessions. This temporary anxiety reduction that results from engaging in a compulsion may have (negative) reinforcing properties that perpetuate the symptom expression in OCD. Similar to avoidance behavior and escape seen in simple phobias, the anxiety reduction served by compulsions may strengthen the stimulus-response connection between obsessions and compulsions. Finally, woven into many compulsions is the "just right" criterion: The individual may engage repeatedly in a ritual or routine or other compulsion until some subjective criterion is reached, so that it feels "just right." Often, however, this sense of the world being just right is short-lived, and the thoughts and behaviors begin all over again.

In many instances, certain obsessions are concomitant with particular compulsions. Germ obsessions commonly accompany hand washing. Particular doubting obsessions are associated with checking compulsions (worry about the stove being left on typically is coupled with checking the stove). The degree to which this obsession-compulsion pairing seems logical to an outside observer varies considerably. One can understand, for example, why someone who fears germs might feel the compulsion to wash. Similarly, it makes some sense for someone concerned that a stove was left on to check the stove. Though clearly in excess (hand washing may occur to the point where the individual's hands are bleeding and he or she is confined to his or her home for fear of contracting disease), there is a certain logic that ties together the obsession and the compulsion.

By contrast, other compulsions in response to obsessions may seem to be less "logically" connected for most

observers. Take, for example, the individual who is plagued with obsessions that his or her parents are going to die in a car crash and who attempts to ward off this imagined event by retracing steps when crossing a threshold. In this case, the connection between the obsession and the compulsion seems more tenuous, as it requires a considerable leap of logic and seems to invoke a greater degree of magical thinking to link the psychological event and the physical behavior. Such magical thinking is present in other disorders as well (e.g., schizotypal personality). The potential difference between the former “logical” obsessive-compulsive behaviors and the latter “magical” obsessive-compulsive behaviors has received virtually no empirical attention but may speak to specific OCD subtypes. We return to this topic in our discussion of normative compulsive-like behaviors in young children. First, we address the clinical entity of OCD.

Obsessive-Compulsive Disorder

OCD is an Axis I disorder in the class of anxiety disorders and is defined by the presence of obsessions and/or compulsions to the point where they interfere significantly with an individual’s daily adaptive, social, or occupational functioning (*Diagnostic and Statistical Manual of Mental Disorders*, fourth edition [*DSM-IV*]; American Psychiatric Association, 2000). The symptoms are viewed as inappropriate and excessive and are of sufficient frequency, intensity, or duration to cause significant subjective distress. The thoughts, impulses, worries, or anxieties that constitute the obsessional thoughts are not generally reactions to real-life situations, or, if they are in reaction to genuine threats, they are grossly excessive relative to the threat. Unlike symptoms associated with thought disorders such as Schizophrenia, the thought disturbances associated with OCD are perceived by the individual as products of his or her own mind (not thought insertion, as with Schizophrenia). Diagnostic criteria also prescribe that significant resistance must exist; that is, in realizing the senselessness of the thoughts or behaviors associated with OCD, the individual makes significant efforts to resist the thoughts and/or behaviors, which are generally unsuccessful.

Constructs such as psychological resistance, subjective distress, and ego dystonia exemplify the psychological turmoil associated with obsessions and compulsions. These constructs require a certain degree of self-understanding, self-perception, and abstract thinking. It is questionable, therefore, whether young children can fully experience resistance and ego dystonia. Because of

this, the insight-related *DSM* criteria (recognition of the excessiveness, ego dystonia) are waived in the current version of the manual (*DSM-IV-TR*, American Psychiatric Association, 2000). Similarly, some debate has surrounded whether children with Autism experience obsessions and compulsions as, presumably, children with Autism are incapable of the metacognitive ability to reflect on their own mental states (Baron-Cohen, 1988). This issue is not fully resolved and has important implications for the definitions of obsessions and compulsions and for the diagnosis of OCD in young children and children with cognitive disabilities.

Table 10.1 represents the *DSM-IV-TR* criteria for OCD. Under these guidelines, an individual must exhibit either obsessions or compulsions that are time-consuming (more than 1 hour per day) or interfere with the person’s normal routine or adaptive functioning. The *DSM-IV-TR* criteria also specify that if the object of certain obsessive, intrusive thoughts is better accounted for by another disorder, then a diagnosis of OCD should not be made. In the case of obsessive thoughts about body image or about foods seen in some eating disorders, an eating disorder or body dysmorphic disorder might be the preferred diagnosis. Similarly, the obsessional state of an individual who is addicted to and preoccupied with alcohol or another drug of abuse would likely be regarded as symptomatic of substance abuse, not OCD.

OCD shares a relatively high comorbidity rate with a great number of other psychiatric conditions, including anxiety disorders, Panic Disorder, simple phobias, mood disorders, and tic disorders. Estimates of OCD comorbidity with other anxiety disorders range from 25% to 75% (Flament et al., 1988; Francis & Gragg, 1996). As many as 83% of patients with OCD report panic attacks (Barlow, DiNardo, Vermilyea, Vermilyea, & Blanchard, 1986). Separation Anxiety Disorder is much more common in older children and adolescents with OCD compared to adults (A. Carter, Pauls, & Leckman, 1996). Mood disorders are found in approximately 25% to 35% of children and adolescents with OCD (Flament et al., 1988, 1990; Last, Perrin, Hersen, & Kazdin, 1992), and some 65% of individuals with OCD also meet diagnostic criteria for depression (Pauls, Leckman, & Cohen, 1994). Tourette’s syndrome is diagnosed in approximately 15% of OCD probands (A. H. Zohar et al., 1992). Conversely, among Tic Disorder probands, OCD is diagnosed in 50% to 70% of cases (Apter et al., 1993; Frances & Gragg, 1996); interestingly, first-degree relatives of patients with OCD are significantly more likely to have a Tic Disorder compared to the general population (Rosario-Campos, in press).

TABLE 10.1 *DSM-IV-TR* Diagnostic Criteria for Obsessive-Compulsive Disorder

p. 672). To receive a diagnosis of OCPD, the *DSM-IV* criteria require that at least four of the following are present: (1) preoccupations with details, rules, lists, order, organization, or schedules to the extent that “the major point of the activity is lost”; (2) perfectionism that interferes with task completion; (3) excessive devotion to work and productivity to the exclusion of leisure activities and relationships; (4) being overly conscientious, scrupulous, and inflexible about matters of morality, ethics, or values; (5) an inability to discard worn-out or worthless objects even when they have no sentimental value; (6) a reluctance to delegate responsibility unless others agree to submit to his or her way of doing things; (7) a miserly spending style toward both self and others; and (8) being overly rigid and stubborn.

In contrast to OCD, in OCPD, the individual does not consciously experience ego dystonicity, a lack of control, or resistance to his or her symptoms. Indeed, there is minimal overlap in the current diagnostic features of OCPD and OCD. Consequently, it is usually easy to distinguish between them. Hoarding behaviors are the only *DSM-IV* criteria for OCPD that may overlap directly with OCD. The diagnoses of OCD and OCPD are not mutually exclusive.

DEVELOPMENTAL TRAJECTORIES OF NORMAL OBSESSIVE- COMPULSIVE BEHAVIORS

Consideration of continuities and discontinuities between normality and psychopathology is a hallmark of developmental psychopathology (Cicchetti, 1993; Cicchetti & Cohen, 1995a; Zigler & Glick, 1986). In this section, we examine a range of normal mental states and behaviors that may inform our efforts to understand OCD. We are intrigued by the possibility that in certain contexts, behaviors that strongly resemble obsessions and compulsions may reflect normative developmental trajectories, serving adaptive functions and stemming from well-conserved vestiges of our phylogenetic roots.

Childhood Rituals

Beginning around the 2nd year of life, most children develop a variety of rituals, habits, routines, and preferences, some of which resemble the behaviors associated with OCD (Evans et al., 1997; Leonard, Goldberger, Rapoport, Cheslow, & Swedo, 1990). The idea that compulsive ritualistic behaviors may be normative in young children is not a new idea. Gesell and his colleagues (Ames, Ilg, & Frances, 1976; Gesell, 1928; Gesell, Ames, & Ilg, 1974) were among the

Obsessive-Compulsive Personality Disorder

Although Obsessive Compulsive Personality Disorder (OCPD) shares the words “obsessive” and “compulsive” with OCD, the clinical manifestations of these disorders are quite different. OCPD is characterized by “a preoccupation with orderliness, perfectionism and mental and interpersonal control, at the expense of flexibility, openness and efficiency” (American Psychiatric Association, 1994,

first to recognize that young children, particularly those around the age of 2½, begin to establish rigid routines that Gesell termed the “ritualisms of the ritualist” (Gesell et al., 1974). Rather than addressing emotional needs, Gesell believed children engage in rituals to master the tasks of a specific developmental epoch characterized by gaining mastery in matters of feeding, toileting, and dressing, among others. Such tasks are facilitated by adherence to rules, and behavioral routines reflect mastery motivation. Developing behavioral routines and habits requires establishing mental representation of behavioral sequences and cognitive schema for the way things “should be” (see also Kagan, 1981). When such expectations are violated, as occurs with interruptions in daily routines or habits, changes in the physical environment or alterations of familiar objects, significant distress may result. In addition to Gesell’s description of children’s elaborate bedtime rituals and the need for sameness, his descriptions of normative ritualistic behaviors include references to “just right” phenomena, as well as pre-occupations with balance, symmetry, and wholeness.

To Freud (1919), the rituals of young children were associated with efforts to control, organize, delay, and resist unconscious sexual impulses directed at their caregivers, which in turn are driven by the child’s wish to be the exclusive focus of the parents’ love and attention. Even normative rituals and compulsions stem from unconscious urges and efforts to reduce anxiety.

Winnicott (1958b) described “transitional objects” and transitional behaviors (e.g., routines and habits) as vehicles by which young children can sustain an emotional contiguity with their primary caregivers. Habits such as the use of and attachment to treasured objects like teddy bears and security blankets reflect the child’s focus on particular objects, and presumably these represent a kind of transfer of parental attachment. That these security blankets and other objects gain particular importance at times of stress is telling in terms of their role in emotion regulation (Passman, 1976, 1977, 1987). Of bedtime routines, Winnicott noted that children engage parents in elaborate rituals, weaving the parents into “a transitional web,” and thus these typical rituals serve to soften the loss of the parent as sleep and separation approach.

Erikson (1968) posited a developmental model of ritualization whereby infancy was characterized by “mutuality of recognition”: a daily bonding ceremonial engaged in by infants and their primary caregivers that gives rise to self-awareness and awareness of self as distinct from other. An infant “signaling” that he or she is awake elicits in the parent a repertoire of emotive, verbal, and manipulative behaviors (Erikson, 1968), such as looking, feeling, and sniffing

as the parent searches for further signals that communicate the subjective state of the infant. The infant reinforces these behaviors by his or her responses. Though Erikson described such behaviors as highly ritualized, they are also individualized and attuned to each dyad. Erikson was clear in his beliefs that such interpersonal rituals in infancy are similar to religious rituals, in that both kinds of rituals involve an affirmation of self and belonging. These parent-child ritualizations “bestow convincing simplicity on dangerously complex behaviors” (p. 205). Rituals, then, simplify and clarify actions to make unambiguous the behaviors and goals in situations in which ambiguity would bring about disorganization and problematic outcomes in terms of the developing self and self-other relationships. To Erikson, rituals are vital to our interpersonal interaction and serve to establish both a sense of self and a sense of self in relation to others.

Though Piaget did not refer specifically to rituals or compulsions per se, his description of the development of cognitive operations certainly shed light on them. Piaget (1962) stressed the role of repetitive movements or circular motor reactions in early development as the child hones innate reflexes into more voluntary actions that aid in the manipulation of and adaptation to the environment. By the end of the sensorimotor period, however, children are able to engage in representational thought, whereby their understanding of the physical world is no longer gleaned through trial and error but by cognitive representations for specific sequences of actions to achieve a goal.

In deferred imitation, children are able to enact a relatively complex sequence of behaviors that they have previously observed. Memory for actions involves encoding a sequence of behaviors culminating in a behavioral totality. So, too, is this the case with sociodramatic play; roles are prescribed, and violations of social roles in play (or in real life) are not easily permitted. Classification and seriation—two hallmarks of the late preoperational and early concrete operational periods—exemplify the child’s abilities to focus on and organize objects according to certain criteria or logical rules. In the preoperational period, children’s understanding of classification and group membership is limited to a single feature. Only later does the child develop the concept that a single object may simultaneously embody multiple features, and depending on the rule of classification, an object may be classified in any number of groups.

A defining feature of compulsivity is the inappropriate perseveration of behavioral patterns. In his well-known experiments demonstrating the development of object permanence, Piaget (1962) noted that young children make

perseverative errors—the A-NOT-B error. That is, they continue to search for an object in a location where it was previously hidden (A), even when they have witnessed the object's being moved to another location (B; Diamond, 1988; Diamond & Taylor, 1996). Prior motor activities are repeated even when the child has been exposed to information indicating that the previous action will be inadequate to retrieve the hidden object. More recently, Zelazo and Reznick (1991; Zelazo & Jacques, 1996) noted that preschoolers will persevere on a sorting task when the sorting rule is switched (say, from color to shape), despite the fact that when asked, they can recall the new sorting rule. Thus, activities that constitute core aspects of compulsivity—sorting, classifying, and arranging objects, and perseveration of previously learned behaviors beyond their adaptive utility—are paramount in the cognitive development of the young child.

Perhaps more clearly than any other scholar of development, Werner (1948, 1957; see Evans, 2000, for a review) devised a comparative and organismic theory that affords a developmental analysis of both typical and atypical development, including rituals and compulsions. Werner explored the processes of mental development in terms of the nature of the organism-environment relationship across a variety of contexts, including childhood, certain cultural practices, and in psychopathology. His belief was that the basic mental and relational patterns of these three apparently disparate contexts could be construed as fundamentally (though not entirely) similar.

Werner recognized that young children often engage in ritualistic, compulsive behavior. To Werner, both normative and pathological rituals reflected a syncretic interaction style—a relative lack of differentiation between the organism and its environment. Put another way, rituals signify a magical connectedness between organism and environment and between thoughts and actions, where “motor and affective elements are intimately merged in the perception of things” (1948, p. 337).

Werner saw rituals as a kind of tool that, in conjunction with magical beliefs, melds the organism and the environment in a complex of causal relations between the ceremonial act and some desired outcome. He viewed magic and ritual as “indissoluble totalities, unitary acts which either fulfill themselves according to an all-or-nothing reaction, or are completely abortive” (1948, p. 344). Cultural rituals, children's rituals, and pathological compulsive rituals involve completion or totality, whereby “any disruption of the form, any failure in the performance—a stumbling, stuttering or even a pause—often occasions a magical inadequacy and inefficacy, since the very magical significance

of the whole event is vital only within an unbroken totality” (1948, p. 344).

Rituals and associated magical beliefs were, to Werner, typical of a level of organism-environment interactions that he defined as perceptual, such that the organism's relation to the environment is relatively fused and undifferentiated. These syncretic modes of interaction may emerge under any number of conditions and are seen as key elements for some of the richest of human experience, such as the basis of emotion and art. Werner differentiated cultural rituals from children's rituals, defining cultural rituals as a “rounded, organized way of life,” (1948, p. 357) whereas children's rituals “can only occupy an isolated position” (1948, p. 357). With this distinction he placed children's rituals in closer proximity to pathological ones, in that, as we will see, the “organization” that is seen in childhood and pathological rituals is not well integrated into their entire repertoire of behavior. Childhood and pathological rituals are, by definition, circumscribed and limited to a particular sphere of life. Werner described the child's world as marked by “unbreakable organization, which occasions and demands rigidity of behavior” (1948, p. 358). These ceremonies invoke all-or-nothing thinking, where the ritual is either carried out properly or not at all.

We all know that during infancy children want to eat and be dressed in some particular habitual fashion. In agreement with this attitude are those ceremonial rules and ritualistic practices of the child. . . . These rituals may be so set that any neglect or alteration is felt to be a symbol of disruption of a state of affairs in which “something is wrong.” . . . We are unable to state definitively just how and when the . . . all or nothing reaction evolves into the formal ceremonial, that is, when it becomes real magical behavior. (1948, p. 359)

According to Werner's (1948) analysis, many of the rituals engaged in by children are in response to some fear or anxiety about the external world or the unknown aspects of sleep, dreams, and the supernatural aspects of the night, such as ghosts and the mystery of the dark. The creation of these rituals, beginning as simple rules come to serve a symbolic meaning that protects the child during sleep (Werner, 1948) and also reflects the child's desire to be protected by rules. In this sense, children's bedtime ceremonies resemble the kinds of compulsive rituals that are seen in Obsessive-Compulsive Disorder: They ward off dreaded events, ensure safety, or, more generally, serve to reduce anxiety states.

Despite numerous references to normative compulsive behavior in young children, the similarities and differences

between normative and pathological compulsive behaviors have been all but absent from the empirical literature. Such analyses may offer insights into the adaptive origins of pathological obsessive-compulsive behaviors, as well as possibly uncovering developmental themes that underlie OCD. Identifying differences in the nature of early developmental rituals in children with and without OCD has obvious practical implications in terms of the early identification and treatment of OCD.

In recent years, Leonard and colleagues (Leonard et al., 1990) explored whether early developmental rituals can distinguish children who later developed OCD from those who did not. These retrospective parental reports suggested that the early developmental rituals in children might have practical implications in terms of the early identification of OCD. The reports suggested that the early developmental rituals of OCD probands and controls were similar when excluding those behaviors that were clearly symptomatic. That is, aside from behaviors such as repetitive hand washing, an act that was clearly thought to be diagnostically significant, the two groups of children did not differ from each other as to their habits and rituals.

Over the past decade, we and others have explored the normative variants of compulsive behavior in young children, including its natural history, and associations with

cognitive development, adaptive behavior, and maladaptive behavior. The first of these studies involved a population-based survey of roughly 1,500 parents with children between 8 and 72 months living in the greater New Haven, Connecticut, area (Evans et al., 1997). An inventory was constructed (the Childhood Routines Inventory, or CRI) that reflected symptoms of Obsessive-Compulsive Disorder but that were cast in a normative framework.

The CRI contains 19 items that fall into two principal components. The first component is composed of items reflecting the repetitive behaviors on the CRI, such as “repeats certain actions over and over,” “prefers the same household schedule or routine,” and “engages in the same play over and over.” The second component includes items that refer to what we call “just right” behaviors: sensory-perceptual phenomena that often involve arranging or rearranging, lining up objects in straight lines or symmetrical patterns, or behaviors woven into a ritual, such that certain behaviors must be repeated until they feel “just right.” “Just right” behaviors also include a heightened sensitivity to slight imperfections in toys or clothes (Evans, Gray, & Leckman, 1999; Evans et al., 1997) and attention to details such as subtle changes in the environment.

In our initial study (Evans et al., 1997), parents indicated on the CRI whether their children engaged in each behavior using a 5-point Likert scale. Figure 10.1 includes

Image rights not available

Figure 10.1 Histograms displaying percentage of children engaging in four of the behaviors assessed by the Childhood Routines Inventory.

the rates of endorsement of selected items on the CRI. The results confirmed our hypothesis that compulsive behaviors on the CRI are prevalent during childhood, especially during the 2nd, 3rd, and 4th years of life (Evans et al., 1997). Specifically, 65% of the 1-year-olds in our sample were said to have engaged in bedtime rituals, whereas 80% of 2-year-olds were reported to engage in elaborate bedtime rituals. The prevalence rates for bedtime rituals remain in the 70% range for 3-, 4-, and 5-year-old children as well (Evans et al., 1997).

Over half of the 2-year-olds in our sample were reported to be “very aware” of minute details, such as imperfections in toys and clothes. Forty-one percent of children under the age of 1 year and 36% of children age 5 were described this way. Seventy-seven percent of parents of 2-year-olds endorsed the item “Is your child a perfectionist?” compared with 29% of children less than 1 year of age and 50% of children age 5 years. Parents of 2-year-olds were also nearly twice as likely to endorse the item “Is very concerned with dirt, cleanliness or neatness” than were parents of 5-year-olds and almost 7 times more likely than parents of children less than age 1. Whereas almost 50% of the 2-year-olds were reported to “insist that certain belongings go in their place,” only 28% of 5-year-olds were reported to do this. Finally, 63% of 2-year-olds were reported to arrange objects until they are “just right” compared to 4% of children >1 year and 41% of 5-year-olds. The findings are also consistent with work by Kagan (1981), who reports that by age 2, children develop standards for the way objects “should be” such that they may become upset when presented with “imperfect” objects, such as a doll with a missing arm (Evans et al., 1999).

Similar results were reported in a smaller sample of 228 Israeli children age 20 to 59 months (A. H. Zohar & Felz, 2001). In terms of the onset of particular compulsive-like behaviors, the following behaviors were the first to emerge: attached to one favorite object (mean onset 13.85 months); preferred the same household schedule or routine every day (15.43 months); had persistent habits (15.80 months); and strong preferences for certain foods (17.14 months). Later emerging compulsive-like behaviors included the following: acted out the same thing over and over in play (24.14 months); collected/stored objects (25.29 months); seemed very aware of/sensitive to how clothes feel (25.92); and has strong preferences for wearing certain articles of clothing (25.92). The Israeli sample studied by A. H. Zohar and Felz displayed similar sequences in terms of the emergence of items on the CRI (the age of onset for the CRI items = 84 months for the two samples). A. H. Zohar and Felz report a mean difference of 3 months in terms of the onset of the U.S. and Israeli samples, however (Israeli means >3 months of U.S. mean ages of onset).

These data suggest that compulsive-like behaviors are a relatively common aspect of normal child development. Ritualistic and repetitive behavior as well as sensory-perceptual, or “just right” phenomena are highly prevalent among children and appear to be most prevalent between the ages of 2 and 4 years. The exact reasons for the emergence of these behaviors are not known, but it seems reasonable to assume—and some data support—that a variety of neurobiological, cognitive, emotional, and social factors contribute to the development of normative compulsive-like behaviors.

Given the assumption that some compulsivity and obsessionalism represents a variant of normative—even adaptive—evolutionarily conserved tendencies in humans and other species, we should see some adaptive correlates of these rituals in young children. A subset ($n = 880$) of our original sample (Evans et al., 1997) was administered the CRI and also a brief version of the Vineland Adaptive Behavior Scales (VABS) assessing children’s adaptive behaviors in the areas of socialization and daily living skills. One might hypothesize that during the period of development when children are particularly prone to engage in compulsive-like behaviors (especially 2 to 3 years of age), these behaviors may serve some adaptive emotional and practical functions. Indeed, it seems to be the case that at ages 2 and 3, children’s compulsive-like behaviors were moderately associated with adaptive behaviors, whereas the associations between compulsive-like behaviors and adaptive behaviors were not significant for children at age 4, and for 5-year-olds correlation coefficients between compulsive-like behaviors and adaptive behaviors were in a negative direction.

As noted earlier in this chapter, some obsessive-compulsive behaviors invoke a certain amount of magical belief such that thoughts and behaviors are relatively fused and undifferentiated. Many obsessive-compulsive symptoms seem to infer causal links between thoughts and behaviors. In two separate studies, researchers noted that the typical compulsions of young children are associated with children’s magical beliefs. In one study (Evans, Milanak, Medeiros, & Ross, 2002), children’s beliefs in the power of wishing and their beliefs in magic were positively associated with compulsive-like rituals and habits. Bolton and colleagues (Bolton, Dearsley, Madronal-Luque, & Baron-Cohen, 2002) also noted that compulsive behaviors are related to magical thinking in children ranging in age from 5 to 17 years.

Some evidence suggests that even in young children, normative compulsivity may be related to emotional development (Evans et al., 1999; A. H. Zohar & Felz, 2001). For children less than 4 years of age, repetitive behaviors were

significantly and positively related to overall fear and to fear of strangers (Evans et al., 1999). Bedtime fears (fear of the dark, of monsters) were related to hoarding objects; fear of death was significantly associated with strong attachment to a specific object; and fear of animals was related to bedtime rituals.

For children older than age 4, a greater number of correlations emerged. Most notably, overall scores on the rituals inventory were related to bedtime fears. “Just right” behaviors were related to fears of contamination and fear of separation; fear of death was positively related to “repeats actions over and over” and “arranges objects” until they are “just right” (Evans et al., 1999).

These findings echo the theorizing of Winnicott, Erikson, and Werner that children’s rituals are associated with anxiety states brought on by the many fears and uncertainties that are common in childhood and that they bear some relationship to the presence of attachment figures as a source of security and syncretic wholeness. These findings also emphasize the range of ritual behaviors and the emerging need young children have to compare elements of the outside world with existing mental representations, as discussed by Gessell and Piaget, so that important aspects of the world are “just right.” These findings suggest that the rituals and compulsions that emerge in normal ontogeny not only are similar to pathological rituals and compulsions, but they may also serve similar functions and represent common fundamental mental processes.

Obsessional Thoughts and Compulsive Behaviors among Older Children and Adolescents

Given the cognitive processing that is involved in obsessional thoughts, it is not surprising that more is known about the development of rituals and compulsions in childhood. Nevertheless, several population-based studies have been completed in children ranging in age from 8 to 17 years (Berg, Whitaker, Davies, Flament, & Rapoport, 1988; A. H. Zohar & Bruno, 1997). A. H. Zohar and Bruno studied one of the youngest cohorts in a large community sample of children in Israel. Children were in grades 4, 6, and 8 ($N = 1,083$) and ranged in age from 8 to 14 years. Among the fourth-grade students, five items from a questionnaire of the Maudsley Obsessive-Compulsive Inventory concerning cleanliness, checking, and guilt about lying were endorsed by more than 50% of the children. Although the level of obsessional thought and compulsive behaviors was significantly lower in the eighth grade than in the sixth and fourth, there was an elevation of children with very high levels in the eighth grade.

A second study employed a survey of the Leyton Obsessional Inventory-Child Version with more than 5,000 non-referred adolescents (Berg et al., 1988). As in the study of younger children, a sizable proportion of the population studied ($>46\%$ of the sample) endorsed one or more obsessive-compulsive symptoms. The items most frequently endorsed were “thinking repetitive thoughts and words,” “hating dirt and dirty things,” “worrying about being clean enough,” and being “fussy” about keeping one’s hands clean. The adolescent girls in this sample endorsed a greater number of obsessional items and had significantly higher interference scores compared to their male counterparts. In this sample, the responses did not differ significantly by the age of the adolescent.

Adult Obsessions and Compulsions

Three independent studies have found that approximately 90% of the normal population report intrusive thoughts whose content is similar, if not identical, to obsessions (Freeston, Ladouceur, Thibodeau, & Gagnon, 1991; Rachman & de Silva, 1978; Salkovskis & Harrison, 1984). In addition to content, the obsessive thoughts reported among normal adults appear to be similar to the obsessions reported among clinical populations in terms of the increased distress associated with the inability to dismiss the thoughts (Rachman & de Silva, 1978; Salkovskis & Harrison, 1984). However, compared with clinical cases of OCD, the obsessions of nonclinical subjects tend to be less frequent, briefer in duration, and more easily dismissed.

Obsessive-Compulsive Features of Early Parenting

There are times in life when adults appear to be more vulnerable to obsessive-compulsive thoughts and behaviors. One of the most distinctive periods surrounds the birth of a child. Winnicott (1958a) described an altered mental state that he termed “primary maternal preoccupation” that characterizes the first weeks of a mother’s relationship with her infant. Suggesting that such a state of preoccupation or a state of “heightened sensitivity” develops toward the end of pregnancy and lasts for the first few postnatal weeks, he likened it to a withdrawn or dissociated state that, in the absence of pregnancy and a newborn, would resemble a mental illness of acute onset. In this period, mothers are deeply focused on the infant to the apparent conscious exclusion of all else, and this preoccupation permits them to anticipate the infant’s needs, learn his or her unique signals, and over time to develop a sense of the infant as an individual. Winnicott emphasizes the crucial importance of such a stage for

the infant's self-development and the developmental consequences for infants when mothers are unable to tolerate such a level of intense preoccupation. Central to our discussion is the described phenomenology of a heightened state of maternal preoccupation centered around the late third trimester and 1st postnatal weeks that usually wanes by the 2nd or 3rd month postpartum as the infant is more socially differentiated.

In a prospective longitudinal study of 82 parents, we have documented the course of early preoccupations and found that they peak around the time of delivery (Leckman et al., 1999). Although fathers and mothers displayed a similar time course, the degree of preoccupation was significantly less for the fathers in our study. For example, at 2 weeks after delivery, mothers of normal infants, on average, report spending nearly 14 hours per day focused exclusively on the infant, whereas fathers report spending approximately half that amount of time. Although the thematic content of these preoccupations includes thoughts of reciprocity and unity with the infant and thoughts about the "perfect" appearance of the infant, anxious intrusive worries concerning the parents' adequacy as parents and the infant's safety and well-being also were commonplace. Virtually all of the parents (>95%) reported recurrent worries about the well-being of their child. More than 80% of the mothers and 70% of the fathers were concerned about the possibility of something bad happening to their baby, including worries about the child's health, development, and appearance. Several parents explicitly mentioned sudden infant death syndrome as the reason they needed to check their infant. The spontaneous narratives recorded at the interview included frequent concerns about the baby falling or being dropped or thrown. One mother described worries about traveling in the car with her infant son and possibly having an accident due to her negligence. Another mother dreamed that her baby had "cuts around her eyes because Mom hadn't cut her baby's finger nails and she had scratched herself." Several parents reported worries about pets or other animals injuring the infant because of some negligence on their part. Consistent with our expectation, a number of parents said such things as, "I tell myself it is ridiculous to think about this, the likelihood is so remote."

Thirty-two percent of the parents (9 mothers and 10 fathers) reported that they had had abhorrent thoughts of harming the infant during the weeks after the birth. A few parents linked their thoughts to the child's demands for attention, such as "When my baby is crying at 2 A.M., I can understand why parents hurt their children." Another father wondered out loud "Am I capable of child molesta-

tion?" However, most of the images focused on acts of negligence, "accidentally dropping the baby or making a mistake by being inattentive." Indeed, one insightful mother initially mentioned that she thought of only other parents harming their babies, but then said, "I guess we are frightened of our aggressive impulses and displace them onto others." In most instances, these were fleeting or momentary thoughts, but seven parents described these thoughts as occurring "occasionally." At 2 weeks after birth, only a small minority of parents report that these unpleasant thoughts are a definite source of interference (10% of both mothers and fathers) or that they caused moderate or severe emotional distress (15% of mothers and 5% of fathers). In response to these anxious or unpleasant thoughts, 59% of the mothers and 42% of the fathers reported that they performed various actions. In this subset of parents, their actions included checking on the baby (60%), talking to others (54%), or making an effort to distract themselves (9%).

Virtually all of the parents (>90%) reported checking on their babies, usually in response to some signal from the infant. However, more than 75% of the parents also described the need to check even though they knew that everything was okay. At this time, nine mothers (22%) and seven fathers (17%) reported that they checked in this compulsive fashion "frequently" or "very frequently." However, only 27% of the mothers and 20% of the fathers recall telling themselves that such compulsive checking was unnecessary or silly. A majority of parents (83% of mothers and 68% of fathers) stated that they would be "moderately" or "severely" distressed if they were prevented from checking on their child.

In this study, we found that 95% of the mothers and 80% of the fathers had such recurrent, anxious intrusive thoughts in the weeks preceding birth. In the weeks following delivery, this percentage declined only slightly to 80% and 73% for mothers and fathers, respectively. At 3 months postpartum, these figures were unchanged. Other investigators have reported similar findings of increased worries that, in particular, may stress relations between the parents as the time for delivery approaches (Cowan & Cowan, 1992). After delivery and on returning home, most frequently cited were concerns about feeding the baby, about the baby's crying, reflecting on the responsibility of caring for the baby, and thoughts about the baby's physical well-being. Conditions such as these are more commonly reported among parents of very sick preterm infants (Goldberg & DiVitto, 1995), infants with serious congenital disorders or malformations, or infants with serious birth complications (Hodapp, 1995).

Even before the child is born parents preoccupy themselves with creating a safe and secure environment for the infant. Major cleaning and renovation projects are commonplace as the human form of nest building unfolds. Uppermost among parental concerns are the safety of their child and their unimpeded access to the child. Safety issues include the cleanliness of the infant's immediate environment. After birth, this same sense of heightened responsibility will compel parents to check on the baby frequently, even when they know the baby is fine. This heightened sense of responsibility and vigilance concerning possible threats to the child's well-being remains a part of parenthood well into the 1st decade and beyond and is a central element of parenthood. For example, as the child matures and becomes more mobile, parents need to child-proof their home to prevent the child's finding toxic chemicals or being at risk for falling down stairs.

EPIDEMIOLOGY AND NATURAL HISTORY OF OBSESSIVE-COMPULSIVE DISORDER

OCD is among the most common psychiatric disorders, with lifetime prevalence estimates as high as 3% and 1-year prevalence rates ranging from 0.5% to 2.1%. These numbers are comparable for both adult and childhood/adolescent OCD (American Psychiatric Association, 2000; Karno, Golding, Sorenson, & Burnam, 1988; Rasmussen & Eisen, 1998; Valleni-Basile et al., 1994; A. H. Zohar, 2001). Modal age of onset is between 6 and 15 years of age for males and 20 and 29 years of age for females (American Psychiatric Association, 2000; Rasmussen & Eisen, 1998).

The natural course of early-onset OCD is variable and often difficult to predict (Flament et al., 1988, 1990; Leonard et al., 1993; Wewetzer et al., 2001). Fluctuations in symptom severity are commonplace and make predictions concerning short-term outcomes unreliable (Lin et al., 2002; A. H. Zohar, 1999). Viewed prospectively, the boundary of the diagnosis of OCD is not always easy to establish, as a significant proportion of childhood-onset OCD cases ascertained at one time point will be judged to be subthreshold at a later time point and vice versa (Berg et al., 1988; Peterson, Pine, Cohen, & Brook, 2001; A. H. Zohar, 2001). Of note is the fact that in several studies of children with OCD, the mean age at onset of compulsions is earlier than the onset of obsessions (Geller et al., 1998; Rapoport, 1989) and differs from the usual pattern seen in individuals with an adult onset. Some investigators have also found that the early-onset individuals are more burdened by compulsions (Rosario-Campos et al., 2001).

A second peak of OCD onset is associated with puberty and the years following. In general, the course of adult OCD shows a range of outcomes: (1) chronic unrelenting; (2) phasic, with periods of complete remission; and (3) episodic, with incomplete remission that allows some degree of normal functioning (Goodwin, Guze, & Robins, 1969; Skoog & Skoog, 1999). Studies vary considerably regarding the proportion of patients in each category, but there are at least 10% who exhibit an unrelenting course.

The development of efficacious pharmacological and behavioral treatments has led to a significant improvement in outcomes over the past 2 decades. However, once present, a vulnerability to disabling obsessions and compulsions is often a lifelong challenge.

OBSESSIVE-COMPULSIVE SPECTRUM DISORDERS

In recent years, there has been a growing popularity of the concept of a spectrum of disorders related to OCD (Hollander, 1993; Rasmussen, 1994). Although there has been some debate about the breadth of membership and the criteria used for inclusion, certain disorders, including chronic tic disorders, Body Dysmorphic Disorder, eating disorders, and Trichotillomania, are routinely considered to be part of this spectrum (Jenike & Wilhelm, 1998).

Initially, the grounds for grouping these disorders rested on clinical impressions of phenotypic similarities such as a failure to inhibit repetitive behaviors and a subjective urge or compulsive need to engage in these maladaptive behaviors (Hollander, 1993; Rasmussen, 1994). Consequently, support linking this spectrum of disorders to OCD has accumulated from a variety of sources. These include epidemiological studies (Cohen et al., 1995; K. A. Phillips, Gunderson, Mallya, McElroy, & Carter, 1998), family genetic studies that have evaluated the recurrence risk in first-degree family members (Bienvenu et al., 2000; Lenane et al., 1992; Pauls, Alsobrook, Goodman, Rasmussen, & Leckman, 1995; K. A. Phillips et al., 1998), neurobiological and neuroimaging studies (O'Sullivan et al., 1997; Peterson, Staib, et al., 2001; Stein, 2000), and studies of treatment response (Goodman, Ward, Kablinger, & Murphy, 1997; Hollander, 1998; K. A. Phillips, 1996; Ravindran, Lapierre, & Anisman, 1999). These data are far from uniform, and a much stronger case can be made for some disorders, such as chronic tic disorders, compared to others. However, this growing body of data is sufficiently compelling that some investigators have hypothesized that some members of this spectrum may be best understood as vari-

ant phenotypes of a common obsessive-compulsive genetic diathesis (Billett, Richter, & Kennedy, 1998; Pauls et al., 1995; Swedo & Leonard, 1992). Alternatively, Yaryura-Tobias and colleagues (2000) have proposed that these disorders might be better classified simply as variants of OCD. This spectrum concept and the accumulating data point to the inherent limitations of current nosological classification schemes and the need for new approaches to gain deeper insights into the genetic and neurobiological origins of these disorders.

EFFORTS TO REFINE BEHAVIORAL PHENOTYPES: SYMPTOM DIMENSIONS VERSUS DISCRETE SUBTYPES

The *DSM-IV* regards OCD as a unitary nosological entity. This parsimony has a certain aesthetic and practical appeal, but it may be misleading. Given the heterogeneity of the clinical picture, course of illness, response to treatment, and emerging neurobiological and genetic findings, investigators have used a variety of approaches to refine this complex set of phenotypes. In this section, we consider these efforts.

Obsessive-Compulsive Symptom Dimensions

The symptoms used to define OCD are diverse. Two individuals with OCD may have totally different and nonoverlapping symptom patterns (Rasmussen & Eisen, 1998). Studies of psychopathology, genetics, neurobiology, and treatment outcomes have frequently and usefully simplified this complex array in several ways, one of which is the use of global severity rating scales such as the Yale-Brown Obsessive Compulsive Scale (Goodman, Price, Rasmussen, Mazure, Delgado, et al., 1989; Goodman, Price, Rasmussen, Mazure, Fleischmann, et al., 1989).

Historically, attempts to classify OCD patients based on their clinical phenotype have met with limited success. Early descriptive efforts yielded a rough topology but lacked a sound empirical basis (Janet & Raymond, 1903/1976; Lewis, 1936). Other difficulties have included the use of symptom inventories that are biased toward specific symptoms such as checking or cleaning or that omit key symptoms such as hoarding, obsessions concerning symmetry or exactness, ordering and arranging obsessions and compulsions, and religious obsessions (Hodgson & Rachman, 1977; Minichiello, Baer, Jenike, & Holland, 1990). As pointed out by Baer (1993) and colleagues, such

biases inherently limit the value of these reports. More problematic was the use of composite severity ratings based on all of the patient's obsessions and compulsions (Fals-Stewart, 1992; Kim, Dysken, Pheley, & Hoover, 1994; McKay, Danyko, Neziroglu, & Yaryura-Tobias, 1995). The use of such composite severity ratings assumes the unity of the OCD construct and loses the rich diversity of symptomatology. Still other studies relied solely on inventories of current symptoms (Baer, 1993; Fals-Stewart, 1992). This approach fails to take into account the changing constellation of symptoms that can be observed over time. Finally, many of these studies have relied on data from a relatively small number of subjects that yield unstable estimates from factor analyses.

Keeping in mind these limitations, earlier studies have consistently paired washing and cleaning compulsions with contamination obsessions. Similarly, aggressive, sexual, and religious obsessions tend to co-occur. Obsessions of symmetry and exactness were found to accompany repeating rituals, counting compulsions, and ordering/arranging compulsions. Similarly, hoarding compulsions often co-occur with hoarding and saving obsessions.

Based on these earlier studies, a series of factor-analytic studies involving more than 2,000 OCD patients have identified at least four obsessive-compulsive symptom dimensions (Baer, 1993; Cavallini, Di Bella, Siliprandi, Malchiodi, & Bellodi, 2002; Leckman et al., 1997; Leckman et al., 2003; Leckman, Zhang, Alsobrook, & Pauls, 2001; Mataix-Cols, Rauch, Manzo, Jenike, & Baer, 1999; Mataix-Cols, Rosario-Campos, & Leckman, 2005; Summerfeldt, Richter, Antony, & Swinson, 1999). One dimension is characterized by aggressive, sexual, and religious obsessions and checking compulsions. A second factor is characterized by obsessions of symmetry and exactness and ordering and arranging compulsions. A third factor includes contamination obsessions and cleaning/washing compulsions, and the fourth factor includes hoarding obsessions and compulsions. In some studies, hoarding symptoms are included with obsessions of symmetry and exactness and ordering and arranging compulsions (Baer, 1993); in other studies, aggressive obsessions and checking behaviors are separate from sexual and religious obsessions (Mataix-Cols, Rauch, et al., 1999).

Preliminary data supporting the validity of these dimensions come from longitudinal studies (Mataix-Cols, Rauch, et al., 2002) in which the strongest predictor of the presence of a particular symptom dimension was having had that symptom dimension in the past. These data suggest that the nature of the obsessive-compulsive symptoms are relatively stable across time, with waxing and waning of

symptoms rarely involving shifts between dimensions. Longer follow-up studies involving larger samples are needed to better understand the fluctuations of OCD symptoms across time.

As discussed earlier, recent data provide evidence for the orderly emergence of similar compulsive traits in normally developing children (Evans et al., 1997; A. H. Zohar & Felz, 2001). Many of the rituals and compulsions of childhood appear to be aligned with obsessions of symmetry and exactness and compulsions involving ordering and arranging. However, elements of each of the factors can be traced to early childhood, including worries about attachment figures and an increased concern about dirt and germs. Similarly, the heightened sensitivity to threat that is seen in new parents can contain preoccupations and behaviors that are congruent with each of these dimensions.

As reviewed in later sections of this chapter, preliminary data supporting the validity of these dimensions come from genetic studies (Leckman et al., 2003; Rosario-Campos et al., 2005; Zhang et al., 2002), functional brain imaging studies (Mataix-Cols et al., 2003, 2004; M. L. Phillips et al., 2000; Rauch et al., 1998), and treatment studies (Black et al., 1998; Mataix-Cols, Marks, Greist, Kobak, & Baer, 2002).

Discrete Subtypes

Investigators have argued that there are some distinctive forms of OCD that are best regarded as discrete subtypes, each with its own natural history, genetic vulnerabilities, neurobiology, and treatment response. Some of the most compelling data concern tic-related OCD, early-onset OCD, and hoarding as discrete subtypes.

Tic-Related Obsessive-Compulsive Disorder

The obsessions and compulsions found in individuals with Tourette's syndrome and other chronic tic disorders cover a broad range in terms of content, intensity, persistence, impairment, degree of perceived ego syntonicity, and relationship to the individual's tic symptoms. A growing number of studies examining symptom type, natural history, sex ratio, family genetic data, neurobiological correlates, and treatment response lend increasing support to the hypothesis that tic-related OCD constitutes a distinctive subtype. Compared to OCD in individuals without a history of tics, this subtype appears to be characterized by an earlier age of onset and a greater proportion of males (King, Leckman, Scahill, & Cohen, 1998; Leckman, Walker, Goodman, Pauls, & Cohen, 1994). They also have a more frequent family history of chronic tics (Grados et al., 2001; Pauls et al., 1995), a worse long-term prognosis (Wewetzer et al.,

2001), higher afternoon plasma prolactin levels and more normal cerebrospinal fluid oxytocin levels (Leckman, Goodman, et al., 1994a, 1994b), and a poorer therapeutic response to monotherapy with serotonin reuptake inhibitors, albeit with marked improvement with the addition of a neuroleptic (McDougle et al., 1993, 1994).

Early-Onset Obsessive-Compulsive Disorder

Most studies have found that early-onset OCD (onset under the age of 12 years), when compared to adult onset, is typically characterized by significantly higher frequencies of tic-like compulsions, sensory phenomena preceding repetitive behaviors, higher probability of comorbid tic disorders or Tourette's disorder, higher rates of OCD and tics among first-degree relatives (Nestadt et al., 2000; Pauls et al., 1995; Rosario-Campos et al., in press), and a poorer short-term treatment response to antiobsessional agents (Rosario-Campos et al., 2001).

Hoarding

Hoarding occurs relatively frequently in OCD, and there is evidence that patients with hoarding symptoms have more severe OCD and are less responsive to treatment (Black et al., 1998; Mataix-Cols, Baer, Rauch, & Jenike, 2000). Hoarders frequently exhibit obsessions of symmetry, as well as counting and ordering compulsions (Samuels et al., 2002). Hoarders also exhibit a high rate of obsessive-compulsive spectrum conditions, including social phobia, personality disorders, and pathological grooming behaviors (skin picking, nail biting, and Trichotillomania). Hoarding and tics are also more frequent in first-degree relatives of hoarding than nonhoarding OCD patients. Genetic linkage data (Samuels et al., 2002; Zhang et al., 2002) and neuroimaging studies support the utility of seeing hoarding as a distinctive subtype of OCD (Mataix-Cols et al., 2004; Saxena et al., 2004).

NEUROPSYCHOLOGY

Recent neuropsychological evidence suggests that patients with OCD perform poorly on some executive function (EF) tasks, which typically involve recruitment of the frontal cortices. Executive functions include goal-directed behavior, sustained attention, working memory, maintaining a cognitive set, and cognitive set shifting, as well as motor inhibition and response suppression (Evans, Lewis, & Iobst, 2004; Schultz, Evans, & Wolff, 1999).

Some evidence suggests that patients with OCD may perform significantly worse on tasks of set shifting (e.g.,

the Wisconsin Card Sort Task [WCST]) relative to normal controls as well as compared to other psychiatric groups (Head, Bolton, & Hymas, 1989; Hollander & Wong, 1995; Hymas, Lees, Bolton, Epps, & Head, 1991; Lucey et al., 1997). For example, OCD subjects make significantly more perseverative errors on the WCST than normal controls (Lucey et al., 1997). In particular, reports of obsessions are linearly related to WCST errors. Still more specifically, OCD patients who exhibit obsessional slowness perform worse on cognitive set-shifting tasks relative to OCD patients not exhibiting obsessional slowness (Gehring, Himle, & Nisenson, 2000). In addition to perseverative errors on the WCST, patients with OCD tend to have longer response latencies on EF tasks (Gehring et al., 2000). Greater response latency may indicate that subjects spend more time generating alternative responses. Patients with OCD may also be more likely to check or doubt their responses on such tasks and to experience greater error detection, which may slow response rates. Longer response latencies observed with OCD patients appear to be limited to these EF tasks and do not generalize to other, non-EF tasks (Behar et al., 1984), as behavioral responses on other tasks can be performed at normal speeds. It seems that only those behaviors that involve linking and sequencing behaviors are slowed in patients with OCD (Galderisi, Mucci, Catapano, D'Amato, & Maj, 1995; Sawle, Hymas, Lees, & Frackowiak, 1991; Schultz et al., 1999). Even within the normal range along the obsessive-compulsive spectrum, obsessive-compulsive behaviors are associated with poorer set-shifting abilities (A.H. Zohar, LaBuda, & Moschel-Ravid, 1995). In a typical sample, scores on the checking factor of the Maudsley Obsessive-Compulsive Inventory are related to perseverative errors and reaction time, though the amount of shared variance is modest. Nonclinical subjects whose self-reported obsessive-compulsive behaviors fall 1 standard deviation above the mean performed poorly on the Tower of Hanoi (TOH; a measure of planning ability), relative to subjects whose self-reports fall 1 standard deviation below the mean on the Maudsley Inventory (Mataix-Cols, Junque, et al., 1999). Both checking behaviors and total score on the Inventory are correlated to number of moves and time to complete the TOH. These findings argue for a continuum approach to OCD, such that similar cognitive deficits associated with OCD may play a role in subclinical obsessions and compulsions (Evans et al., 2004; Schultz et al., 1999).

Still, some question whether set-shifting deficits are peculiar to OCD. In studies employing strict matching strategies (i.e., age, sex, education level, and IQ) between OCD patients and comparison groups, previously observed dif-

ferences on set-shifting tasks disappear (Abbruzzese, Ferri, & Scarone, 1995). Others (e.g., Cox, 1997; Grau, 1991) argue that IQ is a better predictor of performance on the WCST than are the symptoms associated with OCD, suggesting that set-shifting deficits in OCD may have been overestimated in the past (Schultz et al., 1999).

Although the role of set shifting in OCD remains somewhat unclear, findings linking motor inhibition/response suppression and obsessive-compulsive behaviors are more consistent. In a study of children and adolescents with OCD, symptom severity correlated positively with response suppression errors (Cox, Fedio, & Rapoport, 1989; Rosenberg, Dick, O'Hearn, & Sweeney, 1997). Relative to controls, patients with OCD demonstrate poor performance on an oculomotor suppression (antisaccade) task (Rosenberg, Averbach, et al., 1997). These findings are consistent with previous work (Tien, Pearlson, Machlin, Bylsma, & Hoehn-Saric, 1992) noting greater error rate on a goal-guided antisaccade task. The task requires that subjects move their eyes away from, rather than toward, a novel stimulus (Schultz et al., 1999). Several other studies reports similar deficits in patients with OCD on tasks of object alternation, but not on set-shifting tasks. Object alternation tasks require that subjects give a certain response for one stimulus, but not for another, followed by reversal of the response rule (Cavedini, Ferri, Sarcone, & Bellodi, 1998; Gross-Isseroff et al., 1996). Not only do these studies report group differences between OCD and non-OCD subjects, but they also report linear associations between symptom severity and perseverative errors of commission on response suppression/object alternation tasks (Gross-Isseroff et al., 1996), again supporting a spectrum approach to obsessive-compulsive symptoms and associated neuropsychological performance. In sum, research examining EF and obsessive-compulsive symptoms indicates impairment of response suppression and motor inhibition abilities in subjects exhibiting obsessive-compulsive behaviors. The findings are somewhat less consistent on set-shifting tasks. For each of these EF tasks, evidence points to longer response latencies with increasing obsessive-compulsive symptom expression.

To return briefly to the normative development of compulsivity and perseverative behaviors mentioned earlier in this chapter, our recent findings echo some of these interesting associations linking compulsive behaviors and neuropsychological performance (Pietrefesa & Evans, *in press*). Response inhibition and set-shifting abilities, in addition to their association with OCD, undergo important developments during childhood, particularly during the preschool and early school-age years, and presumably as a

function of frontal lobe maturation (Evans et al., 2004; Zelazo & Jacques, 1996). In children less than 6 years of age, errors of commission on a go/no go task (the continuous performance task), as well as errors on a Stroop-like task, were positively related to compulsive-like behaviors, whereas for children over the age of 6 years, errors of commission were negatively associated with compulsive behaviors (Pietrefesa & Evans, *in press*). Response inhibition and compulsivity, which appear to be linked in OCD, are also linked in normative development. At a certain point in normative development, however, the neurobiological structures controlling response inhibition (see later discussion) begin to do their job to effectively organize and regulate behavior (Pietrefesa & Evans, *in press*), whereas earlier in development (and in OCD), impulsivity and compulsivity may be more closely related, reflecting the dysregulation of associated neurobiological structures and functions. These findings are preliminary, however, and require further study.

GENETIC FACTORS

Recent advances in molecular genetics have greatly increased the capacity to localize disease genes on the human genome. These methods are now being applied to complex disorders, including OCD (Hanna et al., 2002; Willour et al., 2004). One of the major difficulties in the application of these approaches is the likely etiologic heterogeneity of OCD and related phenotypes. Heterogeneity reduces the power of gene-localization methods, such as linkage analysis (Alcais & Abel, 1999; Gu, Province, Todorov, & Rao, 1998; Zhang & Risch, 1996). Etiologic heterogeneity may be reflected in phenotypic variability. Thus, it would be highly desirable to dissect the syndrome, at the level of the phenotype, into valid quantitative heritable components.

As reviewed earlier, recent factor analyses have consistently identified several symptom dimensions (Mataix-Cols et al., 2005), two of which are associated with increased familial risk for OCD: aggressive, sexual, and religious obsessions and checking compulsions and symmetry and ordering obsessions and compulsions (Alsobrook, Leckman, Goodman, Rasmussen, & Pauls, 1999; Leckman et al., 2003). Both of these symptom dimensions are also frequently seen in association with Tourette's syndrome (TS).

Using data collected by the Tourette Syndrome Association International Consortium for Genetics (TSAICG) Affected Sibling Pair Study, Leckman et al. (2003) selected all available affected TS pairs and their parents for which

these obsessive-compulsive symptom dimensions (factor scores) could be generated using the four-factor algorithm first presented by Leckman et al. (1997). Remarkably, over 50% of the siblings with TS were found to have comorbid OCD, and greater than 30% of mothers and 10% of fathers also had a diagnosis of OCD. The factor scores for aggressive, sexual, and religious obsessions and checking compulsions and symmetry and ordering obsessions and compulsions scores were significantly correlated in sibling pairs concordant for TS. In addition, the mother-child correlations, but not father-child correlations, were also significant for these two factors. Based on the results of the complex segregation analyses, significant evidence for genetic transmission was obtained for all factors.

More recently, a genome scan of the hoarding dimension was completed using the same TSAICG data set (Zhang et al., 2002). The analyses were conducted for hoarding as both a dichotomous trait and a quantitative trait. Not all sib pairs in the sample were concordant for hoarding. Standard linkage analyses were performed using GENEHUNTER and Haseman-Elston methods. In addition, novel analyses with a recursive-partitioning technique were employed. Significant allele sharing was observed for both the dichotomous and the quantitative hoarding phenotypes for markers at 4q34, 5q35.2, and 17q25. The 4q site is in proximity to D4S1625, which was identified by the TSAICG as a region linked to the TS phenotype. A recursive-partitioning analytic technique also examined multiple markers simultaneously. Results suggest joint effects of specific loci on 5q and 4q.

In sum, the use of quantitative traits that are familial may provide a powerful way to detect the genetic susceptibility loci that contribute to OCD presentations (Alcais & Abel, 1999; Elston, Buxbaum, Jacobs, & Olson, 2000; Leckman et al., 2001; Zhang & Risch, 1996). Thus far, this approach has provided especially promising leads with regard to the hoarding phenotype. Next steps include, first, the use of these symptom dimensions in large multigenerational families to refine the initial genetic linkage results for the hoarding phenotype. Obviously, if specific loci are identified, this will provide compelling evidence for the validity of this multidimensional approach to OCD. Second, genome scans need to be conducted using the remaining obsessive-compulsive symptom dimensions. Families segregating for TS or early-onset OCD may be especially valuable in this enterprise. Given the high mother-child correlations in the Leckman et al. (2003) study, it may also be valuable to examine the linkage results for alleles that are identical by descent from the mother. Third, twin and cross-fostering studies are needed to further evaluate the heri-

tability of these symptom dimensions within the general population. Finally, future genetic studies will need to examine the relationship between these dimensions and other closely related phenotypes, including various eating disorders (Halmi et al., 2003) and Body Dysmorphic Disorder.

Epigenetic Risk and Protective Factors

Pregnancy and the immediate postpartum period is a time of increased risk for the onset of OCD, with rates among women varying from 11% to 47% (Buttolph, Peets, & Holland, 1998; Ingram, 1961; Lo, 1967; Neziroglu, Anemone, & Yaryura-Tobias, 1992; Pollitt, 1957). Most of these cases begin during late pregnancy or a few days to 2 weeks after delivery. Other frequently reported precipitants include a recent move, sexual or marital problems, and the illness or death of a near relative (Ingram, 1961; Lo, 1967; Pollitt, 1957).

NEUROBIOLOGY

Multiple converging lines of evidence indicate that specific neural circuits and neurotransmitter and neuromodulatory systems play a crucial role in the expression of obsessive-compulsive symptoms. After examining the available evidence, we consider the role these circuits and systems may play in the development of normal forms of obsessive-compulsive behavior and raise the question whether OCD is best viewed as a single disorder or as a complex set of vulnerabilities that in one way or another relate to our appraisals of the environment with regard to its safety.

Neural Circuits

Neuroimaging studies have implicated a variety of neural structures, particularly frontal-striatal circuits, in the neurobiology of OCD (Baxter et al., 1992; Insel, 1992; Rauch et al., 1994; Rauch, Savage, Alpert, Dougherty, et al., 1997). Several regions of the prefrontal cortex are presumably involved in executive functions and are implicated in the pathobiology of OCD. Specifically, OCD patients typically show hyperactivity of the lateral orbital frontal cortex (OFC), caudate nucleus, and anterior cingulate cortex (ACC), all three of which are thought to work together to inhibit or terminate inappropriate responses and to select and monitor preferred behavioral sequences. The OFC in particular appears to have a specific role in decision making based on emotional cues (Anderson, Bechara, Damasio,

Tranel, & Damasio, 1999; Bechara, Damasio, Damasio, & Anderson, 1994; Rolls, 2000). Positron emission tomography (PET) studies indicate increased glucose metabolism in the OFC, caudate, ACC, and thalamus (Baxter, 1990; Baxter et al., 1992; Baxter et al., 1987; Nordahl et al., 1989; Rauch et al., 1994; Rauch, Savage, Alpert, Fischman, & Jenike, 1997; Schwartz, Stoessel, Baxter, Martin, & Phelps, 1996). In dense-array event-related potential (ERP) research, OCD patients demonstrate an exaggerated error-monitoring component localized to the region of the ACC (Gehring et al., 2000; see Evans et al., 2004, for a review). In PET studies, symptom provocation in OCD is associated with increases in blood flow to the OFC and caudate (McGuire et al., 1994; Rauch et al., 1994), and functional magnetic resonance imaging (fMRI) work has noted increased activation of the medial OFC, ACC, and caudate as well as the insular cortex and amygdala (Breiter & Rauch, 1996; Breiter et al., 1996).

Successful intervention seems to reduce these activation patterns. Baxter and colleagues (1992; see also Schwartz et al., 1996) observed reductions in glucose metabolism in the OFC and caudate nucleus in OCD patients following a 10-week trial of both pharmacological and cognitive-behavioral therapy. Saxena et al. (2002) found symptom reduction induced by pharmacological therapy to correspond with reduced metabolism in the right lateral-anterior OFC as well as the right caudate nucleus. Thus, not only are the symptoms of OCD associated with orbitofrontal hyperactivation, but perhaps more remarkably, these studies suggest that the causal relation between brain and behavior associated with OCD may be bidirectional (Evans et al., 2004). These brain-behavior relations are thought to characterize children and adolescents as well as adults (Bradshaw & Sheppard, 2000; Santosh, 2000).

The OFC is involved in a broad range of intersecting functions, including cognitive, emotional, and behavioral regulation (Evans et al., 2004). These functions include evaluation of the motivational significance of stimuli, learning appropriate responses to rewarding and aversive stimuli, and adaptive switching of behavioral responses, as well as processing and regulating emotional states (Bechara, Damasio, & Damasio, 2000; Davidson & Irwin, 1999; Rolls, 2000). The OFC also is responsible for its own kind of working memory, including representations of the significance of stimuli and of one's own emotional states. The OFC includes several distinct regions, each unique in its anatomy, connectivity, and cell structure. These regions may be divided into medial and lateral areas. The medial region is involved in reward and incentive motivation and stimulus-response learning; it is more directly connected

to paralimbic and limbic structures involved in emotion regulation (e.g., insular cortex, amygdala, hypothalamus; Evans et al., 2004). The lateral region of the OFC is implicated in behavioral inhibition, response suppression, selection of one response over others (e.g., Bokura, Yamaguchi, & Kobayashi, 2001; Bradshaw & Sheppard, 2000), and the reappraisal (or effortful regulation) of emotional significance (Ochsner, Bunge, Gross, & Gabrieli, 2002). This region is more richly connected to higher neocortical systems, particularly the dorsal lateral prefrontal cortex.

Both the medial and lateral OFC systems are connected to the basal ganglia, including the striatum. The medial OFC is strongly connected to the ventral tegmental area and nucleus accumbens, with which it participates in a circuit controlling basic incentive motivation (Depue & Collins, 1999). The lateral OFC is connected to the caudate nucleus, with which it participates in the coordination of motor activity. Both orbital-striatal streams project to the thalamus, from where they return to frontal and motor cortical systems, comprising feedback circuits that modulate motivation and action. Finally, regions of the OFC are connected to the ACC, another frontal system involved in executive functions. The ACC is involved in overriding prepotent response patterns, self-monitoring and error detection, and selection among competing responses (Botvinick, Nystrom, Fissell, Carter, & Cohen, 1999; C. S. Carter et al., 2000), functions that overlap with the lateral OFC.

As noted earlier, several OCD symptom dimensions have been identified. Despite this phenotypic heterogeneity, only one neuroimaging study thus far has examined the neural correlates of specific OCD symptom factors (Rauch et al., 1998). This study found that a factor comprising aggressive, religious, and sexual obsessions and checking compulsions correlated significantly with blood flow in the striatum bilaterally, whereas a factor of contamination obsessions and cleaning or washing compulsions correlated with blood flow in bilateral ACC, left OFC, and other cortical areas. Symmetry-related and order-related OCD symptoms had a trend toward negative correlation with blood flow in the right striatum. More recently, Mataix-Cols et al. (2004) found a distinct pattern of activation associated with several of the symptom dimensions. Patients viewed in the MRI machine alternating blocks of emotional (washing-related, checking-related, or hoarding-related) and neutral pictures while listening to scenarios related to the content of each picture type. Specifically, OCD patients demonstrated significantly greater activation than controls in bilateral ventromedial prefrontal regions and right caudate nucleus in response to washing stimuli; putamen/globus pallidus, thalamus, and dorsal cortical areas in

response to aggressive/checking stimuli; and left precentral gyrus and right orbitofrontal cortex in response to hoarding stimuli. Although these are preliminary results, they raise the question of whether the heterogeneity in the findings of previous functional imaging studies of OCD could be partially accounted for by phenotypic variations among their subject pools.

Neurotransmitters and Neuromodulators

In addition to imaging studies, pharmacological and neurobiological studies have implicated several central neurotransmitter systems in the pathophysiology of OCD and related conditions. The strongest pharmacological evidence concerns the serotonergic system and the well-established efficacy of potent serotonin reuptake inhibitors in the treatment of OCD (cf. Goodman, Price, Rasmussen, Delgado, et al., 1989; J. Zohar & Insel, 1987). However, other systems also have been implicated. Specifically, central dopaminergic and opioid systems seem to be important in the expression of some forms of OCD (Goodman et al., 1990; Hanna, McCracken, & Cantwell, 1991; Insel & Pickar, 1983; McDougle et al., 1993, 1994; Senjo, 1989). Several studies have implicated two closely related neuropeptides, arginine vasopressin (AVP), and oxytocin (OT), in the pathobiology of some forms of OCD (Altemus et al., 1992; Ansseau et al., 1987; de Boer & Westenberg, 1992; Leckman et al., 1994b; Swedo et al., 1992). Both AVP and OT have been implicated in the manifestation of memory, grooming, sexual, and aggressive behaviors (Leckman, Goodman, et al., 1994b).

OT has been called the “amnesic” neuropeptide because of its action to attenuate memory consolidation and retrieval. This property has led some clinical investigators to administer OT to OCD patients in the hope that it would help to extinguish compulsions. The results of these trials are mixed, with some patients showing slight worsening of obsessive-compulsive symptoms (Leckman, Goodman, et al., 1994b). Animal data suggest that the OT effects on memory are bimodal and site-dependent. Whereas low doses attenuate memory, moderate doses can actually improve memory. Grooming behavior can be elicited pharmacologically with the administration of either AVP or OT. Administered OT shows a clear dose-response relationship: Increased doses lead to more frequent grooming behavior. The pattern of OT-related grooming involves autogrooming of the head and anogenital regions in many species. Given the close association of animal models of grooming behaviors and human compulsions (e.g., hand washing), AVP and OT continue to be of interest as potential mediators of ob-

sessive and compulsive behaviors. Some of the most compelling data in animals concern the role of OT and AVP in parental and affiliative behaviors (Insel & Young, 2001).

The past decade has seen the emergence of a substantial literature indicating that a variety of neuropeptides are also intimately involved in the regulation of these processes (C. S. Carter, DeVries, & Taymans, 1997; Insel & Harbaugh, 1989; Leckman & Herman, 2002; Numan, 1994). For example, in the case of maternal behavior, several studies have reported that OT given centrally (but not peripherally) to virgin female rats induces full maternal behavior within minutes (Pedersen & Prange, 1979). In contrast, blocking central OT pathways using centrally administered antagonists, antisera, or lesions blocks the onset of maternal behavior (Fahrbach, Morrell, & Pfaff, 1985; Insel & Harbaugh, 1989; Pedersen, Caldwell, Johnson, Fort, & Prange, 1985). One key feature of these studies is that OT antagonists do not appear to disrupt maternal behavior *per se*, as the same intervention following parturition when maternal behavior is already established is without effect.

Neurobiological Perspectives on the Development of Normal Obsessive-Compulsive Behaviors

The existence of structural and functional differences, specific pharmacological responses in humans exhibiting clinically significant manifestations of obsessions and compulsions, and neurobiological findings consistent with animal models of obsessive-compulsive behaviors suggest that these biological mechanisms might play a role in the development of normal obsessions and compulsions. To date, however, little is known about the specific neurobiological mechanisms involved in the emergence of ritualistic behavior and obsessional thought. Indeed, it has only been in the past several years that investigators have begun to examine normal subjects in response to stimuli that are known to provoke OC symptoms in vulnerable individuals. For example, Mataix-Cols and colleagues (2003) imaged 10 normal controls while viewing alternating blocks of emotional (normally aversive, washing-relevant, checking-relevant, or hoarding-relevant pictures) and neutral pictures and imagining brief scenarios related to the content of each picture. They found that the normally aversive images activated regions previously identified during symptom provocation in OCD patients (OFC, lateral frontal cortex, ACC, temporal cortex, basal ganglia, thalamus, amygdala, insula), and distinct patterns of neural response were identified that were associated with the anxiety related to each symptom dimension. In another study, Lor-

berbaum and colleagues (2002) examined the areas of brain activation in new mothers after listening to infant cries. They found activation in the ACC, the right OFC, the medial thalamic nuclei, the bilateral mesial prefrontal cortex, and the hypothalamus and central gray extending to the ventral tegmental area and ventral striatal/basal forebrain regions in the vicinity of the nucleus accumbens and the bed of the stria terminalis.

Although there is considerable disagreement about the specific brain regions that may be involved in OCD and/or nonpathological forms of obsessions and compulsions, frontal lobe, limbic cortices, basal ganglia systems, mid-brain, and hypothalamic sites are likely to be involved. Advances in the neurobiology of OCD and other perseverative behavior disorders may shed light on the maturational changes that give rise to repetitive behaviors, intrusive thoughts, and circumscribed interest patterns that are common in the behavioral repertoire of typically developing young children. Studies of normal individuals during specific developmental epochs may be particularly revealing. The model of overactive interrelated threat-detection circuits appears to be heuristically promising across the course of development.

ETIOLOGICAL PERSPECTIVES AND APPROACHES TO TREATMENT

A remarkable diversity of causes has been identified as contributing to the development of OCD, ranging from demonic possession to diversions of psychic energy to unconscious psychological conflicts to dysfunctional habits and faulty appraisals of normally occurring thoughts to neurochemical hypotheses to discrete brain injuries and post-infectious autoimmune responses. Although we remain largely ignorant of the actual causes of this disease, many of these theories have led to specific treatments, some with clear efficacy. In this section, we briefly examine these etiological perspectives as they relate to the phenomenology, natural history, and especially the treatment of OCD. This compilation will also set the stage for an integrative hypothesis offered at a later point in this chapter.

Descriptive Psychiatry and the Origins of Behavior Therapy

Berrios (1996) has nicely reviewed the historical origins of OCD as a nosological category. Focusing mostly on French and German sources in the nineteenth century, he has documented how OCD was successively explained as a disorder

of volition, intellect, and emotions. Janet (Janet & Raymond, 1903/1976; Pitman, 1987b) is often credited with providing the first definitive account of OCD. Although this point is in dispute (Berrios, 1996), Janet did provide one of the first descriptions of what is now termed exposure therapy, including the name itself, as quoted by Baer and Minichiello (1998):

The guide, the therapist, will specify to the patient the action as precisely as possible. He will analyze it into its elements if it should be necessary to give the patient's mind an immediate and proximate aim. By continually repeating the order to perform the action, that is, exposure, he will help the patient greatly by words of encouragement at every sign of success, however insignificant, for encouragement will make the patient realize these little successes and will stimulate him with the hopes aroused by glimpses of greater successes in the future.

Janet's account is of particular interest as it emphasizes the need for the patient to be fully in the present moment and to perform "real actions" involving considerable effort—hallmarks of most cognitive-behavioral interventions in OCD. It is also striking that Janet described OCD as the result of "psychasthenia," a condition that grew out of a state of "incompleteness" (*inachèvement*). Although the actual meaning of these words may be obscure, the fact that he saw this state as leading to a range of conditions, in addition to OCD, including tic disorders and other diagnoses, shows his appreciation for what is now called the obsessive-compulsive spectrum disorders (Hollander, 1993). Janet's call to "give the patient's mind an immediate and proximate aim" resonates with the capacity of the individual to experience a reappraisal of the emotional significance of specific environmental cues via mechanisms active in the OFC and its connections with reward pathways originating in the midbrain.

Unconscious Conflict, the Vicissitudes of Development, and Psychoanalysis

Freud, working in the same era as Janet, came to view OCD as arising from unconscious psychological conflicts, associated with aggressive and sexual urges to hurt, soil, and control that were capable of generating tremendous anxiety. In his famous description of the Rat Man, Freud (1909/1966) described a range of characteristic mental operations, including denial, reaction formation, isolation, magical thinking, doubting, intellectualization, and undoing that he believed served as defenses against the intrusion of these urges into conscious awareness. This theory served

as one of the foundation stones of psychoanalysis, an intensive form of therapy aimed at gaining a deeper understanding of an individual's unconscious drives and defensive maneuvers. Although there is no controlled evidence to suggest that traditional psychodynamic psychotherapy or psychoanalysis is effective in treating the symptoms of OCD, this form of therapy was the standard for several decades, before being replaced over the past 20 years by cognitive-behavioral interventions and pharmacotherapy (Marks, 1987). It also is of interest that Freud's theory was one in which development played a crucial role. Indeed, he saw the overt or concealed tendencies toward cruelty and anal eroticism as reflecting a fixation on or a regression to an earlier stage of mental development. It is perhaps no accident that the normal developmental period that corresponds to toilet training is contemporaneous with the emergence of rituals, habits, and perfectionism in normal young children (Evans et al., 1997).

Learning Theory and Behavior Therapy

The learning theory that has received the most attention in OCD is Mowrer's (1960) two-stage learning theory, which states that anxiety is classically conditioned to a specific environmental event (stage 1, classical conditioning). The individual then uses compulsive or ritualistic behavior to lessen the anxiety. If the compulsion succeeds in reducing anxiety, then behavior is reinforced, making it more likely that the compulsion will be repeated when the anxiety recurs (stage 2, operant conditioning). It is thought that because the individual does not remain in contact with the eliciting stimulus for a sufficient time for the conditioned anxiety to habituate, obsessions persist. This, combined with the anxiety reduction associated with the performance of the compulsions, produces a cycle that is difficult to break.

V. Meyer, Levy, and Schnurer (1974) were among the first to use a technique called exposure and response prevention to successfully treat 15 patients with OCD. A group at the Maudsley Hospital in London that included Rachman, Hodgson, Marks, and Mawson provided evidence from the first controlled trials that systematic exposure to feared stimuli associated with the decision not to perform the compulsion (response prevention; Marks et al., 1988; Rachman & Hodgson, 1980) provided positive results. These initial positive results have been extended and refined over the past 2 decades by several research groups in the United States and Europe (Emmelkamp, 1982; Foa & Goldstein, 1978). Meta-analyses of this technique have confirmed the short- and longer-term efficacy of this tech-

nique (Christensen, Hadzi-Pavlovic, Andrews, & Matrick, 1987; van Balkom et al., 1994).

Rachman and Hodgson (1980) also have tested aspects of this two-stage theory. As predicted, exposure to the stimulus results in an increase in both subjective and physiological indices of anxiety. They also documented that when patients were allowed to engage in their compulsive behaviors, there were measurable reductions in their level of anxiety. These findings, however, appear to be limited to OCD patients with contamination worries and washing and cleaning compulsions. Among OCD patients with checking compulsions, the level of anxiety reduction following checking rituals was less noticeable. Indeed, in 7 of 36 trials, the patients reported an increase in anxiety. These findings are consistent with the view that OCD is not a homogeneous condition. They also raise the question of whether this diversity is best accounted for by identifying discrete subgroups of OCD patients or by using the dimensional approach to obsessive-compulsive symptoms outlined earlier.

Cognitive Theories and Treatments of Obsessive-Compulsive Disorder

Cognitive models of OCD have emphasized problems with threat appraisal and cognitive processing. In the area of thought appraisal, an exaggerated sense of responsibility has attracted the most interest. For example, Salkovskis (1985) has argued that the intrusive thoughts and images characteristic of OCD are nearly universal cognitive events. According to this theory, what distinguishes individuals with OCD is their appraisal of these thoughts rather than their occurrence. Indeed, three independent studies have found that approximately 90% of the normal population report intrusive thoughts whose content is similar, if not identical, to obsessions (Freeston et al., 1991; Rachman & de Silva, 1978; Salkovskis & Harrison, 1984). Other cognitive domains that may contain faulty appraisals include threat estimation, a need for perfectionism, overvaluing of thoughts, a need to control all aspects of one's life, and doubting the veracity of one's sensory experience (Obsessive-Compulsive Cognitions Working Group, 1997). Controlled clinical trials of cognitive therapy for OCD show promise and indicate that cognitive therapy and exposure and response prevention are likely to have similar effects over comparable time periods (Cottraux et al., 2001; van Oppen et al., 1995). Of interest in these comparative trials, exposure and response prevention was found to influence in a positive direction several cognitive indices in these clinical trials, including some having to do with

faulty appraisals of inferiority, guilt, and responsibility (Cottraux et al., 2001).

A second cognitive approach to OCD posits the deficits in basic processes of decision making, attention, and memory. These theories have provided a fertile field for empirical study, but the results thus far are in large part preliminary and have not yielded distinctive approaches to treatment (Steketee, Frost, Rheume, & Wilhelm, 1998).

Taken together, these cognitive deficits and distortions complement and extend the range of obsessive-compulsive symptomatology such that any comprehensive model should take into account the presence of such faulty appraisals, indecisiveness, and loss of confidence in memory or dissatisfaction that is commonplace among OCD patients. They also reinforce the point that through effortful reappraisals of the emotional significance of specific environmental cues, individuals are able to alter their brain activity patterns, as reflected in a decrease in activity of the OFC and its connections following successful cognitive therapies (Schwartz & Begley, 2002).

Medical and Neurobiological Etiologies and Neurosurgical Treatments

As summarized by Jenike (1998), a number of case reports describe the development of obsessive-compulsive symptoms following head trauma, brain tumors, and drug abuse; however, in most of these cases, it is difficult to implicate a particular circuit or brain region. In a second review, Peterson, Bronen, and Duncan (1996) reported three additional cases in which the patient's obsessive-compulsive symptoms showed a worsening during a period of tumor progression. Based on the localization of the lesions, the authors concluded that the limbic system, including the hypothalamus, ACC, and the caudate nucleus, were potentially involved in the neurobiology of OCD. Additional information comes from the work of Laplane and colleagues (1989), who studied eight patients with brain damage due to anoxic or toxic insults and who shared the combination of bilateral basal ganglia lesions and a frontal lobe-like syndrome. Each of the patients showed stereotyped activities with obsessive-compulsive behavior. The bilateral lesions appeared to be confined to the striatum and the globus pallidus. In addition, PET in seven patients revealed hypometabolism of the prefrontal cortex relative to other parts of the brain. Although this is a fascinating series, most of these patients also demonstrated a form of psychic inertia manifested by a loss of drive and a loss of goal-directed behavior, features not

commonly associated with OCD. It is worth noting that the co-occurrence of tic symptoms and stereotypic behavior was not an uncommon clinical feature in many of the case reports cited in this section.

There also is a strong association between OCD and a diverse array of infectious, metabolic, and neuropsychiatric disorders, including von Economo's encephalitis (Claude, Bourk, & Lamache, 1927), diabetes insipidus (Barton, 1965), Huntington's disease (Miguel, Rauch, & Jenike, 1997), Tourette's syndrome (Pauls & Leckman, 1986), Sydenham's chorea (Swedo et al., 1989), and pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (Swedo et al., 1998). Generally speaking, these reports provide further support for OCD being a disease involving the basal ganglia and limbic forebrain as well as hypothalamic and hippocampal regions.

A variety of neurosurgical techniques including the OFC, as in subcaudate tractotomy (Knight, 1972), internal capsule (A. Meyer & Beck, 1954), thalamus, and ACC (Jenike et al., 1991), have been used to treat refractory OCD cases with largely favorable results. These findings lend support to the notion of an OCD-relevant neuronal circuitry extending over all of these structures. Capsulotomy, in particular, is designed to interrupt reciprocal thalamocortical projections contained in the internal capsule and to interfere with a postulated overactivation of the OFC (as reviewed earlier). Of interest, deep brain stimulation using quadripolar electrodes implanted bilaterally in the anterior limbs of the internal capsules has been successfully applied in patients with treatment-refractory OCD (Cosyns, Gabriels, & Nuttin, 2003). Acute deep brain stimulation is reported to result in an immediate improvement of speech, mood, eye contact, and motor function, and chronic deep brain stimulation is reported to improve obsessional and compulsive symptomatology in a majority of patients.

Animal Models

A number of animal models of OCD have been proposed, mostly based on early ethologists' conceptualization of "fixed-action patterns," behaviors necessary for survival that are encoded in the brain as motor (emotive and cognitive) programs that are activated by specific environmental cues, and the concept of "displacement" (out-of-context actions that occur when motivated behaviors cannot be executed; Dodman, 1998). Observed in a wide array of species, the most common classes of displacement activities involve fixed-action patterns associated with grooming, feeding, cleaning, and nest building. These displacement activities

often arise when an animal is faced with a conflict between aggression and escape motivations. Pitman (1991) noted the similarity between the ethologists' observations of displacement activities and Janet and Raymond's (1903/1976) characterization of forced agitations in humans as well as the central role Freud (1909) assigned to conflict in the emergence of obsessive-compulsive symptoms.

These displacement activities have been proposed as an animal model for studying OCD (Dodman, 1998). For example, Greer and Capecchi (2002) have reported that mice with disruptions of a homeodomain-containing gene, *Hoxb8*, show pathological grooming leading to hair removal and lesions. Of interest, these mice excessively groom normal cage mates.

There is considerable comparability between the content of human compulsions and the fixed-action patterns observed across species (e.g., grooming, washing, hoarding, ensuring safety). By their very nature, fixed-action patterns are invariant sequences of behaviors that are both biologically conserved and cued by environmental stimuli. Presumably, such behaviors serve adaptive functions, and for many such behaviors it is easy to comprehend how this may be so. Grooming and washing, for example, have obvious adaptive value in warding off disease and infection, as well as serving potentially adaptive social significance, particularly among nonhuman primates. Hoarding behaviors, too, are not uncommon, and repetitive movements suggestive of vigilance in the process of protecting offspring, for example, are other examples of adaptive repetitive behaviors that may provide keys for understanding pathological repetitive behaviors and associated thoughts.

In addition, the universality of symptoms observed in OCD across cultures and time suggests that compulsive behaviors may represent response tendencies selected through evolution, which become activated out of context in OCD. Although it is important to recognize differences between proximate and ultimate levels of analysis in considering behavioral data, it is also tempting to entertain the possibility that many obsessive-compulsive behaviors represent a kind of run-away selection, such that certain obsessive-compulsive behaviors reflect themes of evolutionary significance. It is possible, for example, that humans are equipped with a biological propensity to engage in certain kinds of repetitive behaviors that represent our phylogenetic legacy, ensuring our biological fitness. There are instances, however, when such behaviors become exaggerated and are performed to excess and in the absence of "appropriate" social or environmental cues, thereby ceasing their adaptive role.

INTEGRATIVE MODEL: THE MELDING OF DEVELOPMENTAL AND EVOLUTIONARY PERSPECTIVES

The full range of obsessive-compulsive symptoms can be normal and adaptive at given points during development. There is a preset neurobiology and presumably a preset group of genes that contribute to these conserved behaviors and preoccupations. Pathological forms of OCD arise when these normal and adaptive systems become dysregulated due to genetic vulnerability, adverse environmental change during the course of development (maladaptive learning leading to brain changes), or brain injury. Viewed in this light, the diverse behaviors and mental states encountered in OCD are not in themselves pathological. It is only by their distress, persistence, and tendency to occupy time to the exclusion of more normal activities that they become pathological.

Evolutionary Perspective on Developmental Psychopathology

Before reviewing the data that support this point of view, an examination of our theoretical model is in order. The principal goal of an evolutionary perspective on psychopathology is to provide a coherent framework from which to view

patterns of maladaptive behavior that are persistent in human populations (Leckman & Mayes, 1998). In such an evolutionary framework, the issue of persistence appears to be paradoxical given the editing power of natural selection. Darwin's (1859/1993) principle of natural selection posits (1) the existence of variation among individuals, (2) differential reproductive success for those individuals who exhibit traits that are useful in "the struggle for life," and (3) differential inheritance of those factors that gave rise to the favorable traits. Why, then, would particular variations persist that place individuals at a reproductive disadvantage in the struggle for life? From our perspective, the answer to this question is that the improbable cascade of evolutionary events that has led to the emergence of our species and our particular set of conserved behavioral and mental capacities also has left us vulnerable to certain forms of psychopathology. By "conserved behavioral and mental capacities," we refer simply to those more or less species-typical potentialities of our species. With regard to OCD, we focus primarily on a limited set of these behaviors (and associated mental states) that include the existence of endogenous brain-based alarm systems that are activated by perceived external threats such as separation from an attachment figure (Table 10.2). Intrinsic to this point of view is the understanding that natural selection is largely powerless to edit out many of these vulnerabilities.

TABLE 10.2 Threat Domains, Conserved Behaviors, and Developmental Epochs Associated with Heightened Sensitivity

Threat Domain	Focus of Concern	Mental State	Behavioral Response	Developmental Epochs
Aggressive	Well-being of self and close family members	Intrusive images or thoughts that contain feared outcomes of separation or loss; among older children and adults, a heightened sense of responsibility	Physical proximity; checking to ensure safety; avoidance of danger	Early childhood: formation of attachment to caregivers; early family life: pregnancy, delivery and care of young children; threats to family members due to injury or other external threats
Physical security	Immediate home environment	Heightened attention to the placement of specific objects in the environment	Checking to ensure that things look "just right" and are in their expected place	Early childhood: initial period of exploration of the home environment by infants and toddlers; early family life: pregnancy, delivery and early childhood; threats to family members due to injury or other external threats
Environmental cleanliness	Personal hygiene; hygiene of family members; cleanliness of the home	Preoccupation with intrusive images or thoughts that contain feared outcomes of being dirty or causing others to be ill; among older children and adults, a heightened sense of responsibility	Washing; checking to ensure cleanliness; avoidance of shared or disgusting items	Early childhood: initial period of selection of items of food and drink by toddlers; early family life: pregnancy, delivery and care of young children; threats to family members due to injury or other external threats
Privation	Essential resources	Preoccupation with intrusive images or thoughts that contain feared outcomes of privation; a heightened sense of responsibility	Collecting items; checking to ensure the sufficient supplies are available	Latency: initial period of collecting; early family life: pregnancy, delivery and care of young children

Our body plans, nervous systems, behavioral repertoires, and mental states are highly constrained. Simply put, the elimination of our vulnerability to certain psychopathological states would interfere with species-specific behaviors and mental states that are essential for the survival and reproductive success of our species.

A Model of the Dynamic Interplay of Threat and Attachment and the Vulnerability to Develop Obsessive-Compulsive Disorder

Here we emphasize the dynamic interplay between threat and attachment. During the evolution of our species, it is likely that unless our forebears were acutely attuned to potential external threats posed by other humans, by predators, by the external manifestations of microbial disease, or by periods of privation due to drought, natural disasters, or internecine conflict, our species would not have survived. Likewise, unless there was a determined effort to nurture and ensure the survival of our family members, most especially our offspring, our species would have died off long ago.

We hypothesize that at the level of genes and neurobiology, there will be a clear linkage between our endogenous alarm systems and our capacity to form attachments and that it is this larger system that is dysregulated in OCD. At the level of overt behavior, we posit that the normal rituals of early childhood reflect the earliest maturation of our capacity to judge and respond to external threats and that this period coincides with the phase in our development when normal children begin to explore more actively their rapidly expanding physical and social world. Although most of our knowledge about the ontogeny of attachment behavior is based on studies conducted during the first 18 months of life, a few naturalistic studies (Blurton-Jones, 1972; Konner, 1976) and a number of laboratory-based studies (Main & Cassidy, 1988; Marvin, 1977; Marvin & Greenberg, 1982) document the normative course of attachment behavior during the toddler and preschool years. Two-year-olds, as they move away from their attachment figures, tend to maintain as much (or more) proximity to their mother as do 1-year-olds (Marvin & Britner, 1999). Toddlers tend actively to monitor not only the mother's movements but also her attention, so that when she is not attending to him or her, the child often does something with the apparent goal of regaining her attention (Schaffer & Emerson, 1964). Subsequently, things change so that most 3- and 4-year-olds, if left to wait with a friendly adult, are able to wait for the attachment figure's return before executing attachment behavior (Marvin, 1977). In tra-

ditional cultures, children maintain very close physical ties with their mother until sometime between 3 and 4 years of age (Konner, 1976). This behavioral transition coincides with the emergence of a child's heightened sensitivity to change in the external world, to performance of rituals to maintain sameness, and to alarm reactions/anxiety when changes in the environment do occur (Evans et al., 1997).

Similarly, parental behavior is a highly conserved set of behavioral capacities that are crucial for reproductive success. As reviewed earlier, in humans this period is associated with intense parental preoccupations (Leckman & Mayes, 1999; Leckman et al., 1999; Winnicott, 1958a). The content of these preoccupations includes intrusive worries concerning the parents' adequacy as parents and the infant's safety and well-being. These thoughts and the harm-avoidant behavior they engender resemble those encountered in OCD. Nursing and feeding are the parental behaviors that are perhaps most associated with a new infant. Women describe breastfeeding as a uniquely close, very physical, at times sensual experience and one that creates a particular unity between the mother and her infant. Cleaning, grooming, and dressing behaviors also carry a special valence inasmuch as they permit closeness between parent and infant and are times for close inspection of the details of the infant's body and appearance. Viewed from an evolutionary perspective, it seems nearly self-evident that the behavioral repertoires associated with early parenting skills would be subject to intense selective pressure (Bretherton, 1987; Hinde, 1974; Hofer, 1995; Stevenson-Hinde, 1994). For one's genes to self-replicate, sexual intimacy must occur and the progeny of such unions must survive. Pregnancy and the early years of an infant's life are fraught with mortal dangers. Indeed, it has only been during the past century that, in Europe, infant mortality rates have fallen from over 100/1,000 live births in 1900 to about 10/1,000 in 1984 (Corsini & Viazzo, 1997). Little wonder, then, that a specific state of heightened sensitivity on the part of new parents would be evolutionarily conserved.

THE MODEL'S HEURISTIC VALUE AND FUTURE DIRECTIONS

The conceptual framework underlying emerging models of brain evolution and normal development provides a powerful framework for understanding aspects of disease pathogenesis. This framework is consistent with the pioneering efforts of investigators such as Darwin (1872), Baldwin (1902), Bowlby (1969, 1973), Waddington (1977), Ekman (1980), and Fiske and Haslam (1997), who have applied

evolutionary and developmental principles to the study of normal variation and/or psychopathology. This model's appeal is that it provides a multidisciplinary framework to view a range of pathological behaviors and related normal behaviors—from genes and environmental stressors to theories concerning the active ingredients in cognitive therapies and the neurobiological substrates they effect. For example, theorists in the area of thought appraisal have identified an exaggerated sense of responsibility as being at the root of OCD; our model links this theory with a rational basis for this exaggerated sense of responsibility in that it is akin to the heightened sense of responsibility that new parents experience with the birth of their children and specifies the neurobiological substrates involved. The natural history of OCD, with the high rate of onset or exacerbation of symptoms associated with the illness or death of near family members, the occurrence of sexual problems and/or marital difficulties, and during late pregnancy and the early postpartum period, also provides circumstantial evidence of a link between OCD and these naturally occurring periods of heightened sensitivity to threat.

Although progress has been slow, due in part to the scope and complexity of the emerging scientific knowledge base, incremental progress can be anticipated that should enrich and refine our emerging models of disease pathogenesis. Future progress is likely to follow in the wake of powerful and promising technologies in genetics, neurodevelopment, neuroimaging, and information processing. Some genes are likely to count more than others (Leckman & Herman, 2002). There may be particular alleles acting alone or together that are lethal for the normal emergence of species-typical behavioral patterns (as may occur in some forms of Autism). In the short term on the genetics front, studies using techniques that have been successfully applied in other complex diseases, such as diabetes, are under way (Botstein & Risch, 2003). It is reasonable to expect the eventual identification of loci and alleles of major and minor effect for OCD. Characterization of the vulnerability alleles should permit the development of animal models using transgenic and gene knock-out techniques (Tecott, 2003). Transgenic studies in which human genes are placed in other genomes (such as *Drosophila* or mice) may be quite revealing. Among other possibilities, they may permit the testing of the effectiveness of novel pharmaceutical agents as well as a deeper understanding of how the expression of these particular alleles constrain the developing nervous system. However, species differences and ethical constraints place a natural limit on the testability of evolutionary and developmental explanations of human psychopathology. Also, the ability to genotype accurately

individual patients with regard to known vulnerability alleles may lead to more accurate clinical predictions of course, outcome, and treatment response. Similarly, the results of neuropsychological, neuroimaging, and other biological studies may become more interpretable by classifying patients according to their respective genotypes. We would also predict that prospective longitudinal brain imaging studies of individuals in the midst of normal periods of development that are associated with heightened threat sensitivities will resemble patients with OCD both in terms of their phenomenology and the neurobiological circuits activated.

Future progress may also depend on the refinement of psychopathological phenotypes. It may well be that decomposing more complex syndromes such as OCD into a small number of component dimensions is a useful strategy. Consequently, the development of a dimensional rating scale for measuring OCD symptom severity across the various domains should provide a more accurate appraisal of patients' long-term course and response to treatment (Rosario-Campos et al., in press). Alternatively, other measurable neurophysiological, biochemical, endocrinological, neuroanatomical, cognitive, or neuropsychological components of OCD dimensions may also serve as useful endophenotypes that exist along the pathway between genetic susceptibility and distal clinical phenotypes (Gottesman & Gould, 2003).

For developmental neurobiologists, the identification of specific epigenetic risk factors should open fields of inquiry concerning the mechanisms responsible for observed effects and how they vary according to the timing and degree of exposure. Again, linking such studies with knowledge of relevant genotypes may be particularly useful in clarifying the nature of the resulting biological constraints on brain development through the use of animal models (Tecott, 2003).

Given the ethical limitations associated with the study of human brain development, many experimental studies cannot be performed. Future simulation studies of neural networks increasingly configured to resemble ensembles of neurons in the central nervous system have promise, particularly when investigators begin to vary connections and configuration of units to reflect changes consistent with those observed in patient groups (Jones, Cho, Nystrom, Cohen, & Braver, 2002). Alternatively, the development of scanning procedures that allow for the performance of experiments in which participants interact with each other while fMRI is acquired in synchrony may permit a more complete exploration of the neural substrates of obsessive-compulsive phenomena in patients and controls.

Clinical Implications

The present conceptualization of neurodevelopment and the factors that selectively influence its course has important implications for the prevention, treatment, and care of individuals with OCD. This conceptualization emphasizes the environment as a crucial factor in designing treatment interventions. Identifying features in the home and educational environments that will allow children to feel secure in their attachment to caregivers and confident in the safety of their home environment should continue to be a major priority for research. However, advances in our understanding of those components of the environment that are most crucial for sustaining successful adaptations will doubtless refine these interventions. Analysis of obsessive-compulsive symptoms across a variety of attachment types in children raised in threatening (i.e., maltreating) environments may provide useful avenues for understanding the role of the environment in the onset and development of repetitive behaviors, such as those associated with OCD.

Finally, aspects of this approach may permit a deeper empathetic understanding of individuals with OCD. Specifically, if some forms of OCD bear some relationship to the mental states associated with highly conserved behavioral repertoires typically encountered in expectant parents (intrusive worries about some misfortune befalling the fetus or infant), it should be easier for clinicians to have a deeper emotional empathy for the anguish the patient experiences as they can relate the patient's symptoms to emotional experiences in their own lives (Leckman & Mayes, 1999). Although these models can be accused of being reductionistic, mindless approaches that neglect the inner worlds of children, some of the emerging models of mental development are compatible with the rich, dynamic complexity of intrapsychic states that we encounter in ourselves and in the consulting room.

Tourette's syndrome (TS) is defined by the presence of chronic motor and phonic tics that wax and wane in frequency, forcefulness and complexity. These tics typically begin in early childhood, continue throughout childhood and adolescence, and attenuate substantially by early adulthood. Various cognitive, behavioral, and emotional disturbances tend to co-occur with TS, including Obsessive-Compulsive Disorder (OCD) and Attention-Deficit/Hyperactivity Dis-

order (ADHD; D. J. Cohen, Friedhoff, Leckman, & Chase, 1992; D. J. Cohen & Leckman, 1994).

TS was first reported in the 1880s by neurologist Georges Gilles de la Tourette (1885), who described several cases of "a disorder of the nervous system characterized by motor incoordination accompanied by echolalia and coprolalia." In the decades immediately following its initial description, TS was thought by neurologists and psychiatrists to be a variant of hysteria or chorea, rather than a distinct entity (Brissaud, 1896; Kushner, 2000). In the mid-1900s, the syndrome was understood in terms of psychoanalytic theories of character, obsessive-compulsive neurosis, and narcissism (Mahler, Luke, & Daltroff, 1945). After haloperidol was shown to be effective in reducing tic symptoms in the 1960s, TS was regarded largely as a disorder of neurochemical regulation (A. K. Shapiro, Shapiro, Young, & Feinberg, 1988a). In the

This work was supported in part by NIMH grants MH01232, MH59139, and MH068318, the Thomas D. Klingenstein and Nancy D. Perlman Family Fund, and the Suzanne Crosby Murphy Endowment at Columbia University. We are grateful to James Leckman and Donald Cohen for their intellectual contributions and friendship over many years that helped to inform the content of this manuscript.

late 1980s and 1990s, attention turned to defining the range of phenotypic expression of TS, as well as to identifying the underlying genetic vulnerability to the disorder (Eapen, Pauls, & Robertson, 1993; Pauls & Leckman, 1986; van de Wetering & Heutink, 1993).

Studies attempting to locate the putative TS vulnerability genes have been largely unsuccessful, however, suggesting that the disorder may not be caused simply by a single genetic anomaly that is present only in those who overtly manifest tic behaviors. Instead, genetic vulnerability to tics may be present in a relatively large percentage of the population but expressed in only a minority of those who carry it. In this model of the pathogenesis of TS, the expression and severity of tic behaviors in those who carry the genetic diathesis are mediated by a number of environmental determinants that act together during critical periods of development to activate tic symptoms (Cohen, 1991; Leckman & Peterson, 1993). Each environmental determinant alone is neither necessary nor sufficient to cause tics, but together, in varying combinations, these determinants contribute to a wide variety of clinical presentations within a spectrum of tic disorders and other semi-involuntary behaviors. Tic symptoms, for example, can lie anywhere on a spectrum of frequency and forcefulness, and the presence of a small number of infrequent, minimally forceful tics probably represents a variant of normal behavior. This conceptualization of TS as a disorder caused by multiple genetic and environmental risk factors, the combination and timing of which determine where on a spectrum of clinical presentations a particular person's symptoms lie, is likely applicable to a wide range of complex neuropsychiatric disorders (Cicchetti & Rogosch, 1996; Kopnisky, Cowan, & Hyman, 2002).

The current model for the pathogenesis of TS has been derived using multiple levels of analysis (Cicchetti & Dawson, 2002), including clinical observations, phenomenological studies, family genetic investigations, and developmental and clinical neurosciences (Cohen & Leckman, 1994; Leckman & Peterson, 1993). Examining TS from these varied perspectives leads not only to a greater appreciation of this particular disorder, but also to a fuller understanding of normal human developmental processes. Because the most important factors affecting human development are necessarily ubiquitous and therefore hard to detect, those factors can be more easily recognized when they are studied in the presence of anomalous central nervous system (CNS) development (Cicchetti, 1984, 1990a, 1990b, 1993, 2003). Indeed, studies of the spectrum of tic disorders have taught us much about the importance of varying genetic vulnerabilities, life experiences, and com-

pensatory processes to the normal development of the CNS. Understanding that multiple environmental factors can contribute to the expression of genetic vulnerabilities will continue to shed light on the response of the CNS to constitutional and environmental stress and will ultimately lead to a fuller appreciation of the mechanisms that compensate for these stressors throughout development.

PHENOMENOLOGY AND NATURAL HISTORY

Understanding the natural history and phenomenology of TS is important in effectively educating, counseling, and treating persons with TS and their families. Furthermore, knowledge of the clinical presentation and phenomenology of TS is crucial for the development of clinically relevant research and appropriate diagnostic instruments. Grasping the full range of phenotypic expression of TS allows for an appreciation of its continuities with normal development and of the ways disordered development can result in functional disability.

Phenomenology

Tics are sudden, repetitive, stereotyped movements or phonic productions that, to varying degrees, mimic normal behaviors. Motor and phonic tics are characterized as either simple or complex. Simple tics are brief, usually lasting less than 1 second, and appear purposeless. Complex tics last longer and usually appear more purposeful. Examples of motor tics include eye blinks, head jerks, shoulder shrugs, and facial grimaces. Phonic tics vary from sniffing, throat clearing, or coughing, to complex speech fragments, including syllables, words, and entire phrases. In extreme cases, patients with TS may exhibit coprophenomena, including the utterance of obscenities and profanities (coprolalia) and, more rarely, the performance of obscene gestures (copropraxia). Although relatively uncommon, coprophenomena are among the most socially disabling symptoms of TS (C. Singer, 1997).

The clinical presentation of tic disorders is highly variable across individuals, such that individuals with completely different, nonoverlapping profiles of tic symptoms can fulfill the same diagnostic criteria for TS. Despite this variability, tic symptoms have been reported to cluster together into one of at least four major groups that may be inherited independently: purely motor and phonic tic symptoms; compulsive behaviors (e.g., touching others or objects); aggressive behaviors (e.g., kicking, temper tantrums); and tapping and absence of grunting (Alsobrook & Pauls, 2002). The group of aggressive tic behaviors

tends to co-occur with ADHD. The simple motor and phonic tic grouping tends to occur more in males than in females. Compulsive phenomena are seen in individuals with an earlier onset of tics and in those who have family members with either ADHD or OCD.

Individual tics can occur either alone or together with other tics in what appears to be an orchestrated pattern. In the short term, tics seem to occur in bouts or bursts, and in the long term, they typically wax and wane in frequency, forcefulness, and complexity. The patterning of tics over time, though difficult to predict, is not random (Leckman, King, & Cohen, 1999). Three tic states exist: a baseline state, consisting of tics of intermediate duration and frequency; a bursting state, consisting of short-duration, high-frequency tics; and a state of relative quiescence, consisting of tics of longer duration and frequency. The baseline intermediate state sustains itself but is vulnerable to interruptions by abrupt switches between bursting and quiescence. This pattern of switching between the extreme states of tic frequency continues until the individual is able to return to baseline once again. The factors that cause the fall from baseline and allow the return to it are currently unknown (Peterson & Leckman, 1998). Although not yet supported by empirical studies, this pattern of bursting and quiescent behavior, which has been observed over minutes to hours, could give rise to the long-term waxing and waning of tics, observed over days to weeks and even months, which has been noted in clinical observation.

A child may not be aware of his or her tics initially but will usually become cognizant of them over months or years. Most adolescents and adults are aware of a "premonitory urge" preceding most, but not necessarily all, tics. A "premonitory urge" is characterized by a sense of increasing tension or discomfort that is relieved temporarily by movement of the muscle groups that produce the tic (Kwak, Dat Vuong, & Jankovic, 2003; Leckman, Walker, & Cohen, 1993; Scahill, Leckman, & Marek, 1995). When these urges can be localized to a specific part of the body, they are identified most often in the shoulder girdle, throat, hands, midline of the stomach, or front of the thighs and feet (Leckman et al., 1993). Although performing a tic may relieve the premonitory urge in the short-term, the individual soon feels a mounting, renewed tension that prompts repetition of the tic. The frequent repetition of this cycle of tension and relief may lead to paroxysms of tics that are both physically and emotionally exhausting.

Individuals with TS are highly attuned to sensory changes within themselves and in their external environments (A. J. Cohen & Leckman, 1992; Leckman et al.,

1999). As was first documented by Gilles de la Tourette (1885), the tics of some individuals may involve copying the behavior (echopraxia) and speech (echolalia) of others and of themselves (palilalia). Some individuals may also experience a premonitory urge as arising in other people or in objects; these extracorporeal "phantom" tics are typically associated with the need to touch the person or object in a particular way (Bliss, 1980; Karp & Hallett, 1996).

Continuity of Tic Phenomenology with Normal Behaviors

Many normal people execute spontaneous movements that resemble motor tics. These movements may involve any part of the body, and they may or may not be associated with a conscious urge to move (Keller & Heckhausen, 1990). Such movements often are noted only through active introspection and conscious attempts to inhibit them.

The continuity between normal motor behaviors and motor tic behaviors is well illustrated by the example of eye blinking. Like tics, blinks can be suppressed voluntarily only for a short time. The urge to blink that results from the voluntary suppression of blinking is typically reported by persons with TS to be similar in quality to the urge to tic.

Simple motor tics often involve the orbital musculature (Nomoto & Machiyama, 1990), and these eye-blinking tics are often the first tic behaviors to appear in a child with TS (A. K. Shapiro et al., 1988b). An abnormal blink reflex has been reported in individuals with TS (Raffaele et al., 2004), and one study found an increased frequency of normal blinking in persons with TS compared to control subjects (Tulen et al., 1999). The frequency of eye blinking has also been associated with the overall number and severity of tics in TS (Karson, Kaufmann, Shapiro, & Shapiro, 1985). These studies support the idea that dopaminergic activity, which modulates central nervous system tonus in normal blinking (Karson, 1983; Kleven & Koek, 1996), may also play a part in tic pathogenesis.

Normal children may exhibit "nervous habits," such as thumb sucking and nail biting, or stereotyped motor behaviors, such as body rocking, that can resemble tics. These behaviors are often semicompulsory, in that children may experience an urge to perform the movements and may resist stopping them. A study of nervous habits and stereotypies in children ages 3 to 6 (Foster, 1998) found these behaviors to be quite common in this age group, with parents reporting thumb sucking and nail biting in 25% and 23% of children, respectively. Their high prevalence rates in children of this age group suggests that these movements

may be part of the normal behavioral repertoires of small children and raise the question of whether they may even serve some kind of adaptive function in motor development.

Stereotyped movements of childhood may persist into adulthood in some individuals. One study found stereotypic behaviors to be common in a college population and showed a positive correlation between the number of stereotypic behaviors and obsessive-compulsive symptoms, perfectionism, and impulsion-aggression (Niehaus, Emsley, Brink, & Stein, 2000). A subset of the individuals with persistent stereotypies experience these behaviors as disruptive to activities of daily living, thereby meeting the criteria for Stereotypic Movement Disorder (SMD) outlined in the *Diagnostic and Statistic Manual of Mental Disorders*, fourth edition (*DSM-IV*). There exists some poorly controlled data suggesting comorbidity of SMD with anxiety and affective disorders (Castellanos, Ritchie, Marsh, & Rapoport, 1996).

The diagnosis of SMD can be difficult to make, as stereotyped movements may closely resemble the tics of TS or the compulsions of OCD. When distinguishing among the three disorders, it is helpful to consider the entire history of the individual, with special attention to any previous history of tics or true obsessions and compulsions. When these symptoms are absent from a patient's history, SMD is the likely diagnosis of exclusion.

The stereotyped movements that tend to most resemble the tics of TS are transient and chronic motor tics. Whether these tic disorders are etiologically related to TS remains controversial, although studies suggest that TS, Transient Tic Disorder, and Chronic Tic Disorder are part of the same disease entity, with TS being the more severe form of the disorder (Golden, 1978; Kurlan, Behr, Medved, & Como, 1988; Spencer, Biederman, Harding, Wilens, & Faraone, 1995). Phenomenologically, transient and chronic tics are similar to, if not indistinguishable from, the tics of TS (Nomoto & Machiyama, 1990), and these less severe tic disorders are present in 5 to 20 percent of the general population (Achenbach & Edelbrock, 1978; Khalifa & von Knorring, 2003; Lapouse & Monk, 1964; Nomoto & Machiyama, 1990; Rutter & Hemming, 1970; Rutter et al., 1974). Transient and chronic tics appear in early childhood, like those of TS, likely as a result of maturational changes in the normal central nervous system. Unlike the tics in TS, however, transient tics by definition disappear within months of their occurrence, suggesting that the normal central nervous system may undergo plastic changes to attenuate tics that may be impaired or absent in TS (Peterson, Leckman, & Cohen, 1995).

Assessing Tic Severity

The most commonly used clinical rating instrument for the severity of tics measures the number, frequency, intensity, and complexity of tics, as well as the degree to which tics interfere with motor or speech acts (Leckman et al., 1989). Other instruments for rating the severity of tics have examined how apparent an individual's tics are to others, and the extent to which others view the individual's behavior or appearance bizarre (A. K. Shapiro et al., 1988b). Videotaped counts of tics have also been used to supplement clinical ratings in medication trials and challenge studies (Chappell et al., 1992; Chappell, McSwiggan-Hardin, et al., 1994; Leckman et al., 1991; Lombroso, Mack, Scahill, King, & Leckman, 1991; E. Shapiro et al., 1989).

Commonly Co-occurring Conditions: Attention-Deficit/Hyperactivity Disorder and Obsessive-Compulsive Disorder

Children with TS frequently experience behavioral problems before the onset of tics. About 40% to 50% of children who present clinically with tics already have a history of being overly active, inattentive, and impulsive (D. J. Cohen et al., 1992; Comings & Comings, 1987a). Approximately 60% of the children who present clinically with such problems have difficulties severe enough to satisfy criteria for ADHD. One study of adults with tics and ADHD showed that the onset of tics was, on average, 6 years later than the onset of ADHD symptoms (Spencer et al., 2001).

ADHD is a heterogeneous clinical syndrome characterized by inattention or distractibility, motor hyperactivity, and impulsivity. Children with ADHD tend to perform poorly on tasks requiring sustained attention, motor inhibition, organization, planning, and complex, multisequence problem solving (Barkley, Grodzinsky, & DuPaul, 1992; Geurts, Verte, Oosterlaan, Roeyers, & Sergeant, 2004; Rucklidge & Tannock, 2002). ADHD often co-occurs with or predicts strongly the future development of Oppositional Defiant Disorder, conduct disorders, affective and anxiety disorders, substance use, and aggressive behaviors (Biederman, Newcorn, & Sprich, 1991; Biederman et al., 1995; Peterson, Pine, Cohen, & Brook, 2001; Pliszka, 2000, 2003; Scahill et al., 1999).

The causal relationship underlying this common clinical association of TS with ADHD has been studied extensively but remains unclear. Some family studies have hypothesized that TS and ADHD are variant expressions of the same genetic diathesis, with both conditions resulting from

disturbances in a shared neural substrate, such as dysfunction of the basal ganglia (Comings & Comings, 1984; Pauls, Leckman, & Cohen, 1993). If tics and ADHD do in fact share the same neural substrate and if dysfunction of this substrate does contribute to their co-occurrence, then the severity of the symptoms of TS and ADHD might be expected to correlate positively with one another, a possibility that has received support from some (Randolph, Hyde, Gold, Goldberg, & Weinberger, 1993) but not all studies. One recent study, for example, found no significant difference in tic severity between children with TS alone and those with TS and ADHD (Sukhodolsky et al., 2003).

Other family studies suggest that some children with TS may inherit their tic disorder and ADHD independently from one another (Pauls, Hurst, et al., 1986; Pauls et al., 1993). These findings suggest that the observed clinical association between TS and ADHD is the likely result of referral bias (Berkson, 1946). Children with ADHD exhibit behavioral problems that prompt parents to seek clinical attention. During that evaluation, these children with ADHD may be more often diagnosed with TS than children with tics alone simply because they are more likely to be brought to a clinic. Alternatively, some children with TS may exhibit ADHD-like symptoms that are not a result of a genetic relationship between the two disorders, but that are in some way a direct consequence of having tics. For example, tics or the need to suppress them might interfere with a child's attentional capacities in the classroom and contribute to the identification and clinical labeling of the child as having ADHD.

Whatever the reason for the common clinical co-occurrence of TS and ADHD, numerous studies have documented clearly and convincingly that ADHD symptoms constitute the main source of cognitive, behavioral, and emotional impairment in children and adults who have TS. Studies of cognitive function in TS suggest that the deficits in visuomotor skills and the impairment in executive functions found in TS may be attributable to co-occurring ADHD (Channon, Pratt, & Robertson, 2003; Harris et al., 1995; Silverstein, Como, Palumbo, West, & Osborn, 1995; Yeates & Bornstein, 1994). One recent behavioral study showed that children with both TS and ADHD, when compared with children with TS alone and with normal controls, had more disruptive behavior, greater functional impairment, and higher levels of family dysfunction (Sukhodolsky et al., 2003). The group with both TS and ADHD did not differ from the ADHD-only group, however, suggesting that the risk for problem behaviors in children with TS derives largely from the presence of ADHD, and not from the tic disorder. Other studies using peer, parent,

and self-evaluations found that children with TS and ADHD tend to be less popular than their peers, exhibiting externalizing behavior problems such as aggression, internalizing behavior problems such as social withdrawal, and poor social adaptation (Bawden, Stokes, Camfield, Camfield, & Salisbury, 1998; Carter et al., 2000; Spencer et al., 1998; Stokes, Bawden, Camfield, Backman, & Dooley, 1991). Children with TS alone, in contrast, appear to exhibit internalizing behavior problems only. All of these studies highlight the potential risks posed by co-occurring ADHD to the neuropsychological profile, behavioral patterns, and emotional stability of children with TS. Early diagnosis of ADHD in children with TS, combined with appropriate educational and psychosocial intervention, may improve developmental outcome in these children (Carter et al., 2000).

Over 40% of clinically referred adult TS patients meet formal criteria for OCD (King, Leckman, Scahill, & Cohen, 1999). OCD is an anxiety spectrum disorder defined by persistent, recurring thoughts, ideas, or images (obsessions) that are perceived as intrusive and distressing. These are usually accompanied by intentional repetitive behaviors (compulsions) that relieve the subjective distress associated with the obsession. OCD symptoms tend to cluster into at least four major groups, which have been identified in factor analyses of OCD (Baer, 1994; Cavallini, Di Bella, Siliprandi, Malchiodi, & Bellodi, 2002; Leckman et al., 1997; Leckman, Zhang, Alsobrook, & Pauls, 2001; Mataix-Cols, Rauch, Manzo, Jenike, & Baer, 1999; Summerfeldt, Richter, Antony, & Swinson, 1999). One of these groups includes aggressive, religious, and sexual obsessions, as well as checking compulsions. Another group comprises obsessions and compulsions that pertain primarily to symmetry and ordering. A third group includes contamination obsessions and cleaning or washing compulsions, and a fourth group includes obsessions and compulsions related to hoarding (Leckman et al., 2003).

Family studies have shown repeatedly that OCD is present in the families of individuals with tic disorders more often than it is present in control families, whether or not the individual with tics has co-occurring OCD (Eapen et al., 1993; Pauls, Leckman, Towbin, Zahner, & Cohen, 1986; Pauls, Raymond, Stevenson, & Leckman, 1991). Conversely, tics are present in the family members of individuals with OCD more often than they are present in control families, whether or not the individual with OCD has a co-occurring tic disorder (Leonard et al., 1992; Pauls, Alsobrook, Goodman, Rasmussen, & Leckman, 1995). This co-occurrence of tic disorders and OCD in families suggests that tics and obsessive-compulsive behaviors repre-

sent variable expressions of the same underlying genetic vulnerability. The probable genetic relationship between TS and OCD in turn suggests that although their phenotypes seem to differ significantly, these phenotypes may be more closely related than they appear to be on the surface. The symptoms of TS and OCD, for example, may lie on a spectrum of semicompulsory behaviors (Jaisoorya, Reddy, & Srinath, 2003; Richter, Summerfeldt, Antony, & Swinson, 2003). Urges to carry out these behaviors mount until they become irresistible, at which point, executing the behaviors brings relief. In this model, symptoms with little or no ideational component may belong to the simple tics of TS at one end of the spectrum, whereas symptoms with a prominent ideational component may belong to OCD on the other end of the spectrum. Complex tics may lie somewhere between these two extremes (Peterson & Thomas, 2000).

The forms of OCD that are related to tic symptoms differ qualitatively from the forms of OCD without a personal or family history of tics. Tic-related OCD, compared with the non-tic-related form of OCD, has an earlier age of onset (in childhood or adolescence rather than in adulthood; George, Trimble, Ring, Sallee, & Robertson, 1993; Holzer et al., 1994; Leckman, Grice, et al., 1994; Leckman, Walker, Goodman, Pauls, & Cohen, 1994), a male preponderance (George et al., 1993; Holzer et al., 1994; Leckman, Grice, et al., 1994; Leckman, Walker, et al., 1994), a weaker response to standard antiobsessional medications (Ackerman, Greenland, Bystritsky, Morgenstern, & Katz, 1994; Ravizza, Barzega, Bellino, Bogetto, & Maina, 1995), fewer washing-, cleaning-, and hoarding-related symptoms (Leckman et al., 2003), and a greater likelihood of first-degree family members having a tic disorder (Leonard et al., 1992; Pauls et al., 1995; Riddle et al., 1990). Preliminary findings from one study of clinically referred adults suggest that tic-related OCD may confer a greater degree of clinical morbidity than either TS or OCD alone. Those with TS and OCD had higher rates of anxiety, mood disorders, disruptive behavior, substance use, and OCD spectrum disorders than did adult subjects with TS or OCD alone (Coffey et al., 1998). Whether these findings from a clinically referred sample of adults generalize to the larger population of individuals who have a lifetime with TS, however, is unclear.

Putative Causal Links of Tourette's Syndrome with Attention-Deficit/Hyperactivity Disorder and Obsessive-Compulsive Disorder

The observed co-occurrence of tic disorders, OCD, and ADHD in clinical samples has led to speculation that these

conditions may share a common etiology. Family studies of clinic patients provide fairly strong evidence that TS and OCD are variable expressions of the same genetic diathesis. The link between these two disorders and ADHD has not been well established in family studies, though some investigators still consider ADHD an additional variable manifestation of putative TS vulnerability genes.

The co-occurrence of TS, OCD, and ADHD in families does not necessarily prove that these disorders are etiologically related, because various biases may affect familial aggregation (Peterson, Leckman, & Cohen, 1995; Shapiro & Shapiro, 1992). Family members, for example, may share certain environmental factors that could predispose them to particular symptoms of TS, OCD, and ADHD, which might then produce an apparent association between the disorders even if the disorders are not actually related. Alternatively, characteristics of parents may affect their tolerance of psychopathology in their children, which might increase the representation of certain families in clinical samples. For example, parents with OCD may be more likely to notice and report tics in their children, thus increasing representation of families with both TS and OCD in clinical populations and in the studies that use clinical samples.

If tics, OCD, and ADHD are in fact intrinsically related, then they should co-occur in the general population without clinical referral bias. Cross-sectional epidemiological studies may not capture a true association, however, because of the differing natural history and course of each disorder. Prospective, longitudinal studies of epidemiological samples would provide the best evidence for or against an etiologic relationship.

One prospective longitudinal study of an epidemiological sample (Peterson, Pine, et al., 2001) has shed some light on the natural history of TS, ADHD, and OCD and the associations among the three conditions throughout childhood and into early adulthood. In this study, tics and OCD were significantly associated with one another, as were OCD and ADHD, during late adolescence and early adulthood. Tics in childhood or early adolescence were predictive of OCD symptoms later in adolescence or in early adulthood. Conversely, OCD in late adolescence was predictive of tics in adulthood. ADHD in early adolescence was only weakly predictive of tics in late adolescence but was more strongly predictive of OCD in adulthood. OCD in late adolescence was predictive of ADHD in adulthood. The strongest associations in these analyses were those of tics with OCD and OCD with ADHD. There were no significant associations between tics and ADHD at any time point.

These findings are consistent with the family genetic studies that suggest an etiologic association between tic disorders and OCD. The common co-occurrence of tics and ADHD that has been observed in referred samples was not found in this epidemiological sample, suggesting that the co-occurrence in clinical populations may be due partly to the complex interactions across development between various psychopathological risk factors, including OCD, other anxiety disorders, mood disorders, and conduct disturbances (Peterson, Pine, et al., 2001). Perhaps most interesting are the independent associations between OCD and TS and between OCD and ADHD. This finding suggests that OCD rather than TS may be the "parent" disorder, and tics and ADHD may represent variable manifestations of an OCD genetic diathesis.

Natural History

TS typically begins in early childhood, with one or several simple tics that are often regarded by parents and teachers as benign habits or odd mannerisms. Tics steadily increase in number, frequency, forcefulness, and complexity, reaching a peak in severity at around age 10 or 11. They then tend to decline gradually in severity throughout adolescence (Pappert, Goetz, Louis, Blasucci, & Leurgans, 2003); in fact, by 18 years of age, about 90% of individuals with TS will experience a substantial reduction in tic symptoms, and over 40% will be free of symptoms (Bloch et al., 2004; Burd et al., 2001; Leckman et al., 1998). Superimposed on this rise, plateau, and decline in the severity of tics through childhood and adolescence is an unpredictable waxing and waning in severity over minutes, hours, days, and weeks.

Onset

The mean age of onset of motor tics in TS and other tic disorders is between 5 and 6 years of age (Leckman et al., 1998), although tics may appear as early as 1 year of age or as late as adolescence (Burd & Kerbeshian, 1987). Late-onset tics in the absence of a family history of tic disorders necessitate a thorough workup for other primary causes. Most commonly, the onset of TS is gradual, with one or several transient episodes of seemingly benign childhood tics or mannerisms. These episodes are then followed by periods of more persistent and severe motor and phonic tics.

The first tics to appear are typically transient, simple motor tics of the face, most commonly eye blinking tics (Bruun, 1988). These initial tics are subsequently replaced by, or sometimes joined by, more persistent, forceful, and complex movements. Motor tics typically progress in a gen-

eral cephalocaudal direction, most commonly affecting other head and neck structures, and less frequently affecting the upper and lower extremities. Phonic tics usually appear several years following the onset of motor tics (Leckman et al., 1999), and follow a similar progression from transient, simple sounds to longer-lasting, increasingly exaggerated and complex words and phrases. Each individual has his or her own unique repertoire of motor and phonic tics, the overall severity of which waxes and wanes in cycles lasting days, weeks, or months. The factors that affect these cycles are as yet poorly defined, although exacerbations of tics have been noted in the context of major losses or other stressors.

Early Intramorbic Course

The progressive worsening of tics in young children typically culminates in a period of peak severity at around age 10, although this period of worst-ever severity can occur as early as 7 and as late as 15 years of age (Leckman et al., 1998). During this period many children become increasingly aware of their tics and begin reporting premonitory urges (Bliss, 1980; A. J. Cohen & Leckman, 1992; Kurlan, Lichter, & Hewitt, 1989; Leckman et al., 1993). About 30% to 60% of older children and early adolescents with TS will also begin to experience obsessional thoughts and engage in compulsive rituals (Leckman, Walker, et al., 1994). Compulsive behaviors commonly appear first, and may often resemble complex motor tics. These compulsions initially are typically not associated with obsessional thoughts (Swedo, Rapoport, Leonard, Lenane, & Cheslow, 1989), although some individuals may express a need for things to feel or look "just right" (Leckman et al., 1993).

Tics and associated behavioral problems may interfere with normal social development in childhood and early adolescence. Schoolchildren with TS are often mocked and socially isolated as a result of their tics, and these children tend to view themselves as less attractive than their peers (Carter, Pauls, Leckman, & Cohen, 1994). Children with TS are in fact usually viewed by classmates and teachers as less popular, more withdrawn, and more aggressive (Stokes et al., 1991) than their peers.

Postpubertal Intramorbic Course

A minority of adolescents may experience a worsening of complex tics, along with an increase in anxiety symptoms, mood disturbances, and aggression toward self and others. Most adolescents with TS, however, experience greater self-awareness of their tics, and an increased capacity for self-regulatory control over unwanted behaviors. Up to

90% of late adolescents experience some degree of attenuation of their tic symptoms. Despite this reduction in tic symptoms, however, many adolescents continue to experience the impaired social development and decreased emotional well-being associated with having suffered tics (Bruun, 1988). Adolescents may also experience continuing morbidity related to OCD, ADHD, or other disturbances that may co-occur with TS.

Adolescents with TS often encounter emotional difficulty during the psychological phase of separation and individuation, as they require but resent the continuing involvement of parents around their tics and related symptoms. Any physical stigma can have profound, adverse psychological effects during adolescence, a time of heightened interest in and awareness of one's body. Thus, the highly visible, audible, and tangible bodily manifestations of TS—the unusual movements, strange utterances, occasionally obscene behaviors, and aggression—can impair the formation and solidification of self-image and identity during adolescence (Peterson, Leckman, & Cohen, 1995). Socialization can continue to suffer (Dykens et al., 1990) regardless of the severity of tic symptoms (Stokes et al., 1991), as many adolescents with TS continue to be perceived by their peers as immature, withdrawn, and aggressive.

Adult Outcomes

The severity of tics typically stabilizes by the early 20s (Bruun, 1988; Erenberg, Cruse, & Rothner, 1987). In rare circumstances, individuals with TS may experience exacerbations of tic symptoms later on in adulthood (Nee, Polinsky, & Ebert, 1982). The severity of tics during childhood and adolescence seems to predict only weakly the severity of tics in adulthood (Bloch et al., 2004), although older adolescents who present with severe tic symptoms may hold a relatively poor prognosis (Leckman et al., 1998).

Most individuals with TS experience an attenuation of their symptoms during adulthood; however, some may continue to have tics and associated learning and behavioral problems. Two studies (Erenberg et al., 1987; Goetz, Tanner, Stebbins, Leipzig, & Carr, 1992) have reported that tics and related symptoms remain in the majority of individuals with TS, but these studies must be interpreted with caution because of a poor response rate on patient surveys (only about 60% identified eligible subjects participated in the interviews) and absence of characterization of nonrespondents. One recent but unreplicated study using objective measures of tic symptoms found that 90% of a sample of adults who had been clinic patients as children still had tics, although the tics had improved substantially since childhood (Pappert et al., 2003).

Difficulties Predicting Outcome

Predicting the longitudinal course of TS for a specific individual is not yet possible, although general predictions can be made using the known natural history of the disorder. Tic symptoms that begin early in childhood can be expected to peak in severity sometime in late childhood or pre-adolescence. For most individuals, tics will gradually improve through late adolescence and early adulthood, with a substantial reduction in the number and severity of symptoms (Bloch et al., 2004; Burd et al., 2001; Leckman et al., 1998; Pappert et al., 2003).

EPIDEMIOLOGY

Epidemiological studies have sought to estimate the prevalence and distribution of TS and related tic disorders in the general population. TS and other tic disorders have been documented across all races, ethnic groups, and socioeconomic classes. Transient simple motor and phonic tics are quite common, occurring in 4% to 24% of school-age children (Jankovic, 1997; Khalifa & von Knorring, 2003; Kurlan et al., 2001; A. K. Shapiro et al., 1988b; H. S. Singer & Walkup, 1991; Snider et al., 2002). Chronic tic disorders are much less common, occurring in 1% to 2% of the general population (H. S. Singer & Walkup, 1991). TS is the least common tic disorder, with an estimated prevalence of 0.03% to 0.6% of the population. Tic disorders are found predominantly in males, with a male-to-female ratio ranging from 1.6:1 to 9:1 (Apter et al., 1993; Burd, Kerbeshian, Wikenheiser, & Fisher, 1986; Caine et al., 1988; Comings, Himes, & Comings, 1990; Khalifa & von Knorring, 2003).

The wide range of prevalence estimates reflects various methodological difficulties in conducting epidemiological studies of tic disorders (Peterson, Leckman, & Cohen, 1995). First, samples for these studies have been ascertained from different populations, including patients in mental health clinics, community surveys using self-reports or physician reporting, and recruits in obligatory military service. Ascertainment from mental health clinics has yielded prevalence estimates an order of magnitude larger than the estimates found in ascertainties from community surveys. Second, the ages of sample populations have varied widely across studies. Studies of children tend to produce higher prevalence estimates compared with studies of adolescents and adults, likely because the typical attenuation in the severity of tic symptoms during adolescence reduces the number of positive identifications in temporal cross-section. Third, studies have used different

diagnostic instruments to identify individuals with tic disorders. Studies that rely on self-reports and parental questionnaires for identification of tic behaviors probably underestimate the prevalence of TS because children or their parents tend to underreport symptoms, especially mild ones. Studies that rely on identification from clinical samples overestimate rates of TS and co-occurring illnesses because individuals with more severe tics and more co-occurring conditions are more likely to seek clinical attention (Berkson, 1946).

One of the most methodologically sophisticated epidemiological studies of TS to date (Apter et al., 1993) used a three-stage procedure to diagnose affected 16- and 17-year-old recruits in the Israeli army. These recruits constitute the vast majority of the Israeli population in that age group. TS was diagnosed in 0.043%, with a male-to-female ratio of 1.6:1. The strengths of this study include the direct assessment of tics by an expert clinician in the final stage of ascertainment, the large sample size (>28,000 recruits), and the sampling of virtually the entire population of the country in that age range. The study probably underestimated the lifetime prevalence of TS in that population, however, because the sample consisted only of adolescents, whose tics likely had already improved by that age. Furthermore, young people in Israel generally take pride in their military service and may underreport medical conditions that may adversely affect their possible placement in the more desirable branches of service. Finally, although the study sample did represent the majority of Israelis in the 16- to 17-year-old age group, a minority population of religious women who do not serve in the military was systematically excluded.

A recent epidemiological study of TS examined all 4,479 schoolchildren ages 7 to 15 living in a small Swedish town (Khalifa & von Knorring, 2003). A three-stage procedure was used to identify those with tic disorders. In the first stage, parents completed a screening questionnaire about their child's symptoms. In the second stage, positive respondents from the first stage were interviewed to confirm or refute the diagnosis. In the third stage, children who were confirmed in the second stage as having tics were examined by a trained clinician. A tic disorder was diagnosed in 6.6% of the population, and boys were affected 1.6 times more often than were girls. The prevalence of TS was 0.6%, with a male-to-female ratio of 9:1. Both the prevalence estimate and the male-to-female ratio of TS in this study were considerably higher than those reported in the Israeli army study, probably because the Swedish sample studied the full age range during which TS symptoms emerge, peak, and subside. The higher propor-

tion of boys with TS compared with those who have any tic disorder may suggest that boys are more likely to have a tic disorder that is chronic and that involves both movements and vocalizations.

In light of the limitations of cross-sectional studies and the uncertainties that they confer on lifetime prevalence estimates for tic disorders, prospective, longitudinal studies of representative, community samples are needed to provide more accurate estimates of tic disorders over a lifetime. One study followed 976 children residing in upstate New York for 15 years (Peterson, Pine, et al., 2001). The lifetime prevalence of TS was approximately 0.4%, a value within the range of those reported in previous studies (Costello et al., 1996; Nomoto & Machiyama, 1990; Verhulst, van der Ende, Ferdinand, & Kasius, 1997). More prospective, longitudinal studies of samples representative of the general population are needed to clarify further the prevalence of TS, other tic disorders, and associated conditions.

HEREDITY AND GENETIC VULNERABILITY

In his original reports, Gilles de la Tourette hypothesized a role for hereditary factors in the etiology of TS; for the next century, however, the genetics of TS were largely ignored. The past few decades have seen a renewed and intense interest in the multigenerational transmission of tic disorders (Kidd, Prusoff, & Cohen, 1980). Evidence for a strong genetic role in the expression of TS symptoms has come from twin and family studies, the results of which have prompted association and genetic linkage studies seeking to identify the gene or group of genes involved in TS.

Twin Studies

Studies of twins have suggested that genetic factors are important in the transmission and expression of TS and related disorders. Monozygotic twin pairs have been found to be highly concordant for TS (50% to 90%) and for other tic disorders (77% to 100%; Hyde, Aaronson, Randolph, Rickler, & Weinberger, 1992; Price, Kidd, Cohen, Pauls, & Leckman, 1985; Walkup et al., 1988). Although sample sizes of dizygotic twins have generally been smaller than those of monozygotic twins, the concordance rates for TS (8%) and other tic disorders (23%) in dizygotic twins are much lower than the rates in monozygotic twins. This difference in concordance between monozygotic and dizygotic twins strongly implicates genetic factors in the etiology of TS.

Family Studies

Numerous studies of large numbers of families have been completed in recent years: five in American or European families (Eapen et al., 1993; Hebebrand, Klug, et al., 1997; Pauls et al., 1991; van de Wetering & Heutink, 1993; Walkup et al., 1996) and one in Japanese families (Kano, Ohta, Nagai, Pauls, & Leckman, 2001). All of these studies used direct, structured interviews of probands with TS to obtain information regarding tics and co-occurring disorders. First-degree relatives of probands were also interviewed whenever possible, and best-estimate diagnostic procedures were used to make a consensus diagnosis in these family members.

These studies all report a significantly higher frequency of tic disorders in first-degree relatives of TS probands compared to rates in control samples or in the general population. In the studies using American and European samples, the prevalence of TS among first-degree family members ranged from 10% to 15%, and the prevalence of other tic disorders ranged from 15% to 20%. The first-degree relatives of the Japanese probands, compared to the American and European samples, had significantly lower rates of TS (2%) and other tic disorders (12%). These data, if replicated, may suggest a different etiology of tic disorders in the Japanese population compared to Western populations (Pauls, 2003).

Mode of Genetic Transmission

Segregation analyses seek to identify the pattern of transmission of a disorder within families. The majority of segregation analyses of TS families suggest that major genes play an important role in the expression of tic disorders. Several studies have reported autosomal dominant transmission of the TS genetic diathesis (Eapen et al., 1993; Pauls & Leckman, 1986; van de Wetering & Heutink, 1993), whereas others have proposed a semidominant pattern of inheritance with greater penetrance in affected homozygotes than heterozygotes (Hasstedt, Leppert, Filloux, van de Wetering, & McMahon, 1995; Pauls et al., 1991; Walkup et al., 1996). One study also suggested multifactorial (polygenic) inheritance of TS (Walkup et al., 1996).

Some studies have raised the possibility of a more complex pattern of inheritance for tic disorders. The phenomenon of imprinting, for example, has been implicated as a complicating factor in the genetics of TS. One study (Lichter, Jackson, & Schachter, 1995) examined the TS phenotype of subjects with clear matrilineal and patrilineal inheritance of the syndrome. Subjects with matrilineal in-

heritance of TS tended to exhibit complex motor tics and ritualistic behaviors more frequently than those subjects with patrilineal inheritance. Subjects with patrilineal inheritance had more frequent phonic tics, an earlier onset of phonic tics relative to motor tics, and more prominent ADHD symptoms, including motor restlessness. Although these findings have yet to be replicated, this study illustrates the increasing complexity of the genetics of TS as this field of inquiry evolves. The mechanisms underlying the inheritance of TS are likely to be multifaceted, involving a number of different vulnerability genes.

Searching for Vulnerability Genes

Association and genetic linkage are the two major types of study design that have been used in the search for the TS vulnerability genes. In genetic association studies, a sample of individuals affected with a disease is compared with a sample of unaffected individuals, and the frequency with which certain alleles are present in each of these groups is tested for correlation with the disease. The major advantage of these studies is that a specific mode of inheritance does not need to be assumed in the analysis. The major disadvantage to association studies is their susceptibility to false-positive results, which can be minimized in part by matching the race and ethnicity of all subjects as closely as possible (Gelernter, Pauls, Leckman, Kidd, & Kurlan, 1994; Pauls & Tourette Syndrome Association International Consortium on Genetics, 2001). If precisely matching the control and patient populations on relevant demographic characteristics proves too costly or difficult, investigators may use the haplotype relative risk method (Falk & Rubinstein, 1987; Terwilliger & Ott, 1992) or the related transmission disequilibrium test (Spielman & Ewens, 1996) to study gene-disease associations. Rather than drawing affected and unaffected samples from the general population, these methods examine the DNA of affected probands and their parents. The proband's two alleles constitute the "affected" group, and the alleles that were not transmitted from the parents to the proband form the "unaffected" group. Because both parents donate alleles equally to the affected and unaffected groups, the groups are matched perfectly for race and ethnicity (Pauls, 2003).

The principle of genetic linkage states that genes located close to one another on a chromosome tend to be transmitted together during meiosis, the process of cell division by which germ cells are produced. In genetic linkage studies, members of families are examined to determine whether DNA marker regions that have known

chromosomal locations cosegregate with a disease within the family. If a particular marker is found in family members affected with a disease but not in unaffected members, then that marker is assumed to be sufficiently close to the disease allele such that the marker and the disease are inherited together (Pauls & Tourette Syndrome Association International Consortium on Genetics, 2001). If linkage is demonstrated, the identified area on the chromosome is probed further to locate more precisely the region of interest and, ideally, to identify the specific gene that confers vulnerability to the disease.

Most genetic linkage analyses have studied large, multi-generational families. Although these families do provide a valuable sample of affected and unaffected members, the statistical methods used in these studies require specification of a particular mode of inheritance. In diseases for which the mode of inheritance is unclear or heterogeneous, as is likely the case with TS, misspecification of inheritance parameters can lead to inaccurate or invalid results. Alternatively, many investigators now commonly compare the number of alleles at a given locus that are shared by two affected siblings (sib pairs; Kruglyak & Lander, 1995). Although sib-pair studies are statistically less powerful than are traditional linkage studies, they do not require specifications about the pattern of inheritance of a disease, making them effective tools for the study of diseases whose precise modes of inheritance are unknown. Sibling-pair studies can provide important preliminary information that can be used to direct more statistically powerful approaches (Pauls & Tourette Syndrome Association International Consortium on Genetics, 2001).

Findings

In light of the generally positive response of people with tics to neuroleptic medications, TS has long been suspected to involve central dopaminergic pathways. Because of this hypothesized etiological connection, the various dopamine receptor genes have, to date, been the most frequently targeted genes for directed analyses in association studies. Association has been excluded between TS and the dopamine receptors DRD1 (Chou et al., 2004; Gelernter et al., 1993; Thompson, Comings, Feder, George, & O'Dowd, 1998), DRD3 (Devor, Dill-Devor, & Magee, 1998; Diaz-Anzaldúa et al., 2004; Hebebrand et al., 1993), and DRD5 (Barr, Wigg, Zovko, Sandor, & Tsui, 1997). One study reported an association between TS and DRD2 (Comings et al., 1991), but others have failed to detect such an association (Devor et al., 1990; Diaz-Anzaldúa et al., 2004; Gelernter et al., 1990; Nothen et al., 1994). Two studies have detected a possible association between

TS and the DRD4*7 allele of the DRD4 dopamine receptor (Diaz-Anzaldúa et al., 2004; Grice et al., 1996), but other studies have failed to replicate these findings (Barr, Wigg, Zovko, Sandor, & Tsui, 1996; Hebebrand, Nothen, et al., 1997). Studies attempting to associate TS with the dopamine transporter gene (SLC6A3) have also been unsuccessful (Diaz-Anzaldúa et al., 2004; Gelernter, Vandenberg, et al., 1995; Vandenberg et al., 2000). One recent study (Diaz-Anzaldúa et al., 2004) detected a possible association between TS and the monoamine oxidase-A (MAO-A) gene in a French Canadian founder population, but these results have not been replicated to date.

A number of other candidate genes have been excluded to date, including the 5HT7 serotonin receptor gene (Gelernter, Rao, et al., 1995), the 5HT1A serotonin receptor gene (Brett, Curtis, Robertson, & Gurling, 1995), the alpha-1 subunit of the glycine receptor gene (Brett, Curtis, Robertson, & Gurling, 1997), the adrenergic receptor genes ADRA1C and ADRA2A (Xu et al., 2003), and the Rett syndrome (MeCP2) gene (Rosa, Jankovic, & Ashizawa, 2003). In light of recent theories concerning a possible autoimmune etiology of TS, one study examined the HLA-DRB alleles in 83 unrelated family trios but failed to detect any association between this locus and a diagnosis of TS (Schoenian et al., 2003).

Chromosomal translocations have been detected in some individuals with TS, and several studies have examined possible associations between TS and these disrupted chromosomal regions. Two studies, for example, have reported an apparent association between TS and a translocation between chromosomes 7 and 18 (Boghossian-Sell, Comings, & Overhauser, 1996; Comings et al., 1986). A study examining chromosomes 7 and 18 in 15 multigenerational Dutch families failed to replicate these findings (Heutink et al., 1990). Translocations in persons with TS have also been identified between chromosomes 3 and 8 (Brett, Curtis, Robertson, Dahlitz, & Gurling, 1996) and between chromosomes 1 and 8 (Matsumoto et al., 2000), but on closer examination these translocations were not shown to be significant in the etiology of tic disorders.

A recent study has renewed interest in chromosome 18 as a possible site for the TS vulnerability genes. An inversion between chromosomes 18 and 22 was described in a young boy with chronic tics and OCD, and characterization of the disrupted interval identified two structurally normal transcripts (State et al., 2003). However, further analysis of the region and its products revealed significantly delayed replication timing of the inverted chromosome compared to control subjects. In other words, the inversion produced normal transcripts and proteins, but the rate of transcrip-

tion of the abnormal chromosome was slowed. The results of this study have yet to be replicated, but the findings suggest that chromosome 18 warrants further investigation in the search for the genes responsible for TS.

Early genetic linkage analyses assumed that TS is a homogeneous condition, that it is genetically related to chronic tic disorders, and that it is transmitted in an autosomal dominant pattern. Over thirty multigenerational families have been studied to date, and more than 95% of the genome has been excluded from linkage under these assumptions (Heutink et al., 1995; Pakstis et al., 1991; Pauls et al., 1990). Given these resoundingly negative findings, the Tourette Syndrome Association International Consortium for Genetics (TSAICG; 1999) conducted a sib-pair study consisting of 76 families and 110 sibling pairs. Although no results reached statistical significance, two major regions of interest were identified with MLS scores of greater than 2.0, one on chromosome 4 and the other on chromosome 8.

Other linkage studies have identified various chromosomal regions of preliminary interest. One genome scan of a sample of South African Afrikaners with TS found evidence for linkage on chromosomes 2, 8, and 11 (Simonic, Gericke, Ott, & Weber, 1998; Simonic et al., 2001). Another study of several multigenerational families with TS detected evidence for linkage on chromosomes 5 and 19 (Barr et al., 1999). Notably, the region identified on chromosome 19 in this study also showed moderate evidence for linkage in the TSAICG sib-pair study. A study of a large French Canadian family with TS (Merette et al., 2000) identified a region of interest on chromosome 11, in the same region of this chromosome that was implicated in the South African study. A recent study of two large independent pedigrees with TS (Paschou et al., 2004) detected evidence for linkage on chromosome 17, in regions of the chromosome that were also implicated in a study of a large pedigree from Utah (Leppert et al., 1996) and in a study of sib-pairs with TS who were concordant for the obsessive-compulsive phenotype of hoarding (Zhang et al., 2002).

Though identification of a putative TS gene or group of genes would undoubtedly advance the research of tic disorders, it would be only a small step toward elucidating the neurobiology of TS. The pathways leading from the vulnerability genes to disordered protein production, abnormal cellular functioning, and the disordered structure and functioning of neural systems that give rise to tic-related behaviors will still need to be defined. Knowledge of the genetic basis of TS will not easily or immediately answer the most pressing clinical questions concerning TS, including what factors contribute to exacerbations and remissions of tic

symptoms, what coping strategies are determined by an individual's response to tic symptoms, and what determinants affect the natural history and long-term prognosis for any given individual. Answers to such questions can be gleaned through a combination of genetic, epigenetic, molecular biological, and neuroimaging studies.

ENVIRONMENTAL DETERMINANTS

The expression and severity of tics in an individual are determined not only by an underlying genetic susceptibility to tic disorders, but also by numerous non-genetic determinants in the individual's environment before, during, and after birth. Some possible non-genetic determinants that have been studied to date include prenatal and postnatal exposure to excess androgens, previous infection with Group A Beta Hemolytic Streptococcus, adverse perinatal events, exposure to stimulant medications, comorbid psychiatric conditions, and stressful life events. Although these determinants have been reported to affect the development and severity of tics and related behaviors, their precise contributions to the TS phenotype remain unclear. Further research is needed to identify additional environmental determinants, and to elucidate the influence of each individual determinant on the pathophysiology of tic behaviors.

Sex Hormones

Tic disorders tend to occur predominantly in males, suggesting that sex-specific determinants may either predispose males to developing tic behaviors or protect females from developing them. Clinical observations support a role for sex steroid hormones in modulating the severity of tics (G. M. Alexander & Peterson, 2004). First, tics typically peak in severity shortly before or during puberty, a time when gonadal androgen production increases significantly in both males and females. Second, some women experience more severe tics during the estrogenic phase of their menstrual cycle (Kompoliti, Goetz, Leurgans, Raman, & Comella, 2001; Schwabe & Konkol, 1992). Third, administration of androgens to adults has been reported to worsen tics (Leckman & Scahill, 1990), whereas blockade of androgen receptors has been shown to attenuate them (Peterson et al., 1994; Peterson, Zhang, Anderson, & Leckman, 1998).

Previous studies involving manipulations of androgen levels in adults have supported a role for postnatal sex hormones in the pathophysiology of tics. A recent study, however, suggested that an altered androgen-dependent

differentiation of the brain during prenatal development may also play an important part in determining the severity of tics in later life. In this study (G. M. Alexander & Peterson, 2004), the cognitive functioning and sex-specific behaviors of a large sample of children and adults with TS were compared with those of a group of matched control subjects. The study found that females with TS were more gender-dysphoric, preferred more "masculine" styles of play, and showed a more "masculine" pattern of performance on two sex-typed spatial tasks than did female controls. Furthermore, males with TS showed more "masculine" play preferences than did male controls, the magnitude of which was associated positively with the severity of tics. These findings resemble those reported previously in children with confirmed pathological elevations in prenatal androgen levels. This hypothesized androgenization before birth presumably affects organizational processes in the genome and in brain architecture that are activated by either normal or elevated circulating hormone levels during late childhood and adolescence in individuals who develop tics (Peterson et al., 1992; Peterson, Zhang, et al., 1998).

In light of the evidence suggesting a role for sex steroids in the pathophysiology of TS, imaging studies have sought to identify disturbances in sexual differentiation of the brain that might contribute to the expression and severity of tics. One study of regional brain and ventricular volumes in TS (Peterson, Staib, et al., 2001), for example, reported that the normal differences between males and females in volume of the parieto-occipital cortices were decreased in persons with TS. Whereas this region was larger in female controls than in male controls, its size in females with TS was similar to that of male controls and of males with TS. Because smaller volumes of the parieto-occipital cortex were associated with severity of tic symptoms in this study, a profile more like males in this area of the brain could possibly render females with TS vulnerable to more severe tics. Recent unpublished neuroimaging data also suggest that parietal and limbic regions in females with TS are morphologically similar to those of normal males (B. S. Peterson, personal communication to A. Spessot, January 5, 2004). This similarity suggests that more "male"-typed brain structures may predispose females to tic behaviors.

Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcus

Pharyngeal infection with group A Beta hemolytic streptococcus (GABHS) may produce an autoimmune response that, if it occurs in the CNS, can cause a range of fluctuat-

ing neuropsychiatric symptoms, including tics, obsessions, compulsions, hyperactivity, and distractibility, and that are collectively subsumed under the acronym PANDAS (Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcus; A. J. Allen, Leonard, & Swedo, 1995; Swedo et al., 1997, 1998). The symptoms of PANDAS are generally indistinguishable from those of TS, OCD, and ADHD, suggesting that these latter conditions may in some instances share an autoimmune etiology. Several preliminary clinical studies have supported this possibility by reporting a temporal relationship between GABHS infection and the onset of tic and OCD symptoms in some individuals, as well as improvement in some cases in response to immune-suppressing therapies (Kiessling, Marcotte, & Culpepper, 1993; Kondo & Kabasawa, 1978; Matarazzo, 1992).

Several immunological studies support the nosological construct of PANDAS and also suggest an autoimmune etiology for wild-type TS and OCD. First, elevated levels of antibodies have been detected against basal ganglia structures, both in living children with TS following GABHS infection and in postmortem samples from patients with TS (Kiessling, Marcotte, & Culpepper, 1993; Kiessling et al., 1994; Morshed et al., 2001; H. S. Singer et al., 1998). Furthermore, serum IgG from persons with TS, when infused into rodents, has been reported to produce stereotyped motor movements and vocalizations (J. J. Hallett, Harling-Berg, Knopf, Stopa, & Kiessling, 2000). Lastly, PANDAS patients as well as patients with wild-type TS and OCD may be more likely than controls to express D8/17, a putative B-cell marker for rheumatic fever and other autoimmune sequelae of infection with GABHS (T. K. Murphy et al., 1997; Swedo et al., 1997). Some recent literature disputes these immunological findings. One study, for example, found little to no difference in the levels of anti-basal ganglia antibodies in children with PANDAS compared with controls (H. S. Singer et al., 2004).

Despite this modest preliminary evidence suggesting the existence of a subtype of TS that has an autoimmune etiology, little evidence exists to suggest that TS and related disorders are a direct consequence of GABHS infection. The onset of tics and GABHS infection, for example, are likely to occur in close temporal proximity simply by chance. Because many children are unaffected carriers of GABHS, and because the onset of tic and OCD symptoms in children is often acute, it would not be uncommon to find children with acute tic or OCD symptoms who are GABHS-positive via throat culture or serum antibody testing (Bodner & Peterson, 2003). As a common and stressful illness in children, GABHS pharyngitis may precede tic ex-

acerbations owing simply to the stress sensitivity of tic symptoms (Chappell, Riddle, et al., 1994; Kurlan, 2001).

Elevated levels of antineuronal antibodies have not been found consistently in TS patients, nor have they been absent consistently in normal control subjects. Thus, antineuronal antibody studies in TS (Kiessling et al., 1993; H. S. Singer et al., 1998; Trifiletti, 1998; Trifiletti, Altemus, Packard, Bandele, & Zabriskie, 1998) have not yet proven that antibodies are directed against brain tissue in persons with TS more than in control subjects. Furthermore, even if those antibodies are ultimately deemed elevated in persons with TS, that association may be caused by some underlying, as yet unknown, process, such as a disruption of the blood-brain barrier that could increase antibody levels nonspecifically in the CNS (Bodner & Peterson, 2003). Double-blind, controlled, longitudinal studies are needed to clarify the associations, if any, between GABHS pharyngitis, antineuronal antibodies, and the onset or exacerbation of tic symptoms.

Perinatal Events

Various environmental factors affecting mothers and their fetuses during the perinatal period may influence the expression and severity of TS and co-occurring disorders. One early study, for example, reported that birth complications were more common in children with TS than in controls (Pasamanick & Kawi, 1956). A more recent twin study identified low birthweight as a risk factor predisposing children to tics of greater severity than those occurring in children of normal birthweight (Leckman et al., 1987). Another study (Leckman et al., 1990) found a significantly higher rate of obstetrical complications in mothers of individuals with TS than in the general population. Severe maternal nausea and vomiting in the first trimester, for example, accounted for 50% of the variance in the severity of tics in children. Severity of maternal life stress during pregnancy was also associated with the severity of tics and with the level of overall psychosocial functioning in children with TS. Perinatal events that have been associated with an increased risk of developing co-occurring OCD in persons who have TS include delivery by forceps and prenatal exposure to tobacco, alcohol, or caffeine (Santangelo et al., 1994).

The reported associations of obstetrical complications with the subsequent development of TS or of more severe illness do not prove that the obstetrical complications cause or worsen the severity of TS. Although these complications may injure the CNS and thus contribute to the development of tics, an alternative interpretation of the data is also plausible,

in that the genetic diathesis to TS may interfere with prenatal development in some unknown way and thereby induce or increase the risk for perinatal complications (Walkup, 2001).

Exposure to Stimulants

Some studies have suggested that exposure to the stimulant medications used to treat symptoms of ADHD may also exacerbate tic symptoms (Klein & Bessler, 1992; Mesulam, 1986). Recent long-term studies, however, show no clear or consistent effect of stimulant medications on severity of tics in most children with tic disorders and co-occurring ADHD (Gadow, Sverd, Sprafkin, Nolan, & Ezor, 1995; Gadow, Sverd, Sprafkin, Nolan, & Grossman, 1999; Tourette's Syndrome Study Group, 2002; Wilens et al., 2003). One well-designed, randomized controlled trial suggested that stimulants improve not only ADHD symptoms, but also the symptoms of TS (Kurlan & Tourette's Syndrome Study Group, 2000). Despite this encouraging data from controlled trials, extensive clinical experience and single case studies suggest that an ill-defined subgroup of patients with tics and ADHD that is not captured in group statistics may indeed experience a dramatic worsening of tics in response to use of stimulant medications (Peterson & Cohen, 1998; Walkup, 2001). Children with TS who are being treated with stimulants for co-occurring ADHD should therefore be monitored closely for changes in tic severity.

Life Events and Co-occurring Psychiatric Conditions

Persons with TS appear to be more vulnerable to the adverse effects of stressors in daily life, and they often experience worsening of tic symptoms during times of duress (Chappell, Riddle, et al., 1994; Walkup, 2001). Whether co-occurring psychiatric disorders affect tic severity is unclear. Clinical experience suggests, however, that the treatment of mood and anxiety disorders in persons with TS can often improve dramatically the severity of tics, presumably by reducing the overall emotional burden and psychosocial stress associated with those illnesses.

NEUROBIOLOGICAL SUBSTRATE

The symptoms of TS are thought to arise from anatomical and functional disturbances in cortico-striatal-thalamo-cortical (CSTC) circuits (G. E. Alexander & DeLong, 1985; Baldwin, Frost, & Wood, 1954; Graybiel & Canales,

2001; Kelley, Lang, & Gauthier, 1988; Maclean & Delgado, 1953; Mink, 2001). These circuits contain numerous partially overlapping but largely parallel pathways that direct information from nearly all regions of the cerebral cortex to the basal ganglia and thalamus, and then back again to specific cortical regions (G. E. Alexander, DeLong, & Strick, 1986). The cortical portions of CSTC circuits presumably contribute to self-regulation of behaviors, including the regulation of tic behaviors, by modulating activity in the basal ganglia and thalamus, which in turn modulate activity in the cortex (Goldman-Rakic, 1987; Leung, Skudlarski, Gatenby, Peterson, & Gore, 2000; Peterson et al., 2002). Although the number of pathways remains controversial (G. E. Alexander, Crutcher, & DeLong, 1990; Goldman-Rakic & Selemon, 1990; Parent & Hazrati, 1995), current consensus holds that CSTC circuitry has at least four anatomically and functionally distinct components: those initiating from and projecting back to the sensorimotor cortex, the orbitofrontal cortex (OFC), the limbic and associated anterior cingulate cortices, and the association cortices. Converging evidence from many investigational modalities suggests that motor portions of CSTC circuits are primarily involved in the pathophysiology of tics, OFC portions of the circuits are involved in OCD, and association portions of the circuits are involved in ADHD.

Anatomical Basis

The components of CSTC circuits have long been implicated in the pathophysiology of tic disorders. Electrical or chemical stimulation of the basal ganglia has been shown to produce movements in animals and humans that resemble tics (G. E. Alexander & DeLong, 1985; Baldwin et al., 1954; Kelley et al., 1988; Maclean & Delgado, 1953). Lesions such as tumors in the ventral nuclei of the thalamus have been shown to worsen tic symptoms (Peterson, Bronen, & Duncan, 1996), and surgical lesions in the ventral, medial, and intralaminar nuclei of the thalamus have been shown to attenuate tics (Korzen, Pushkov, Kharitonov, & Shustin, 1991; Rauch, Baer, Cosgrove, & Jenike, 1995). Electrical stimulation of the ventral intermediate and ventral oralis posterior nuclei of the thalamus during surgery has also been reported to produce sensations similar to the premonitory urges that are experienced by many persons with TS prior to performing tics (Tasker & Dostrovsky, 1993). Similarly, electrical stimulation of the supplementary motor area can produce urges to move in normal people that may be similar to premonitory urges (Fried et al., 1991; Lim et al., 1994).

Though studies using methods such as electrical stimulation have implicated indirectly the roles of CSTC components in producing tics, only recently have neuroimaging technologies demonstrated directly the involvement of these components in the pathophysiology of TS. By providing a window into the structure and function of the brain *in vivo*, neuroimaging technologies have revolutionized the study of TS, offering new clues about the brain structures that are inherently dysfunctional in the disorder, as well as about the mechanisms used to compensate for and suppress tic symptoms. The main imaging modalities used to study TS are magnetic resonance imaging (MRI), positron emission tomography (PET), and single photon emission computed tomography (SPECT). The latter two techniques, which require exposure to radiation, are not used in children for ethical reasons. Most imaging studies of TS populations, therefore, have used anatomical and functional MRI to image the brains of children.

The first functional MRI (fMRI) study of TS (Peterson, Skudlarski, et al., 1998) sought to define the contributions of individual components of CSTC circuits to the voluntary suppression of tics. In this study, adult subjects with TS were asked to alternate between 40 second epochs of being allowed to tic freely and 40 second epochs of suppressing their tics. The images obtained while tics were being suppressed were compared with those obtained when subjects were allowed to tic spontaneously, and the magnitudes of signal change in the images were then correlated with various measures of tic severity. Signal intensity increased significantly in the prefrontal cortex and in the caudate nucleus during epochs of tic suppression, whereas signal intensity decreased significantly in the putamen, globus pallidus, and thalamus during these periods. The increased frontal activity detected during tic suppression was associated with the increased caudate activity, a finding that is consistent with the known excitatory projections from the frontal cortex to the caudate nucleus. Increased caudate activity was in turn associated with greater decreases in activity of the putamen, globus pallidus, and thalamus, a finding that is consistent with the known inhibitory projections between the caudate and these other subcortical structures. The magnitude of the increase in activity of the prefrontal cortex did not correlate significantly with the severity of tics, whereas the magnitudes of the decreases in activity of the caudate and other subcortical nuclei were inversely correlated with severity of tic symptoms outside of the MRI scanner. Given the known flow of information between the cortical and subcortical components of CSTC circuits, the correlations between tic

severity and subcortical activity were interpreted as downstream effects of correlations established upon entry into subcortical portions of the circuit, specifically in the projections into or out of the caudate nucleus. The greater the malfunction of these projections into or out of the caudate, the more severe the individual's tic symptoms were likely to be outside of the scanner.

This implication that the caudate nucleus is the origin of functional disturbances in CSTC circuitry is consistent with a recent anatomical MRI study of basal ganglia volumes in a sample of children and adults with TS compared with a sample of matched control subjects (Peterson et al., 2003). Smaller basal ganglia volumes were detected in both children and adults with TS compared with controls, and further analyses revealed that these volume abnormalities were specific to the caudate nucleus. Adults with TS were found to have smaller basal ganglia volumes than children with TS, reflecting smaller volumes of the putamen and globus pallidus in adults but not in children with TS. Basal ganglia volumes were not significantly associated with the severity of tics.

These anatomical findings shed some light on the role of the basal ganglia in the pathophysiology of TS. First, the significantly smaller caudate nuclei in both children and adults with TS suggested that hypoplasia of this structure might represent a morphological abnormality inherent to TS. Second, the decreased volumes of the putamen and globus pallidus that were observed in adults but not in children with TS, by definition, were not generalizable to the larger population of individuals with TS, as most persons with TS experience a substantial reduction in tic symptoms in adolescence and early adulthood. Thus, the decreased metabolism and blood flow in the putamen and globus pallidus of adults with TS (Braun et al., 1993; Hall, Costa, & Shields, 1990; Klieger, Fett, Dimitopoulos, & Karlan, 1997; Moriarty et al., 1995; Riddle, Rasmussen, Woods, & Hoffer, 1992) reported in PET and SPECT studies likely reflect the generally smaller volumes of these structures in adults with TS. The PET and SPECT findings are therefore probably not generalizable to populations of children with TS, in whom volumes of these structures are normal (Spessot, Plessen, & Peterson, 2004).

While anatomical and functional MRI studies have implicated the caudate nucleus as the site of a morphologic trait abnormality in TS, these studies have also suggested that the cortical components of CSTC circuits are involved in the expression and regulation of tic symptoms in those with a diathesis to tics. The first study measuring the volumes of cortical regions in individuals with TS compared a

sample of children and adults with TS to a sample of matched control subjects (Peterson, Staib, et al., 2001). Overall cortical volumes in the TS group were larger than those in the control group, reflecting primarily the presence of larger dorsal prefrontal volumes in both males and females with TS. Within the TS group, however, the larger dorsal prefrontal volumes were observed in children, but smaller volumes were detected in adults. Moreover, larger volumes of the orbitofrontal and parieto-occipital regions were significantly associated with decreased severity of tics. These inverse correlations of prefrontal volumes with severity of tics suggest that the larger cortical volumes in children with TS may represent an adaptive or compensatory process that helps to attenuate tics. This latter possibility is supported by the findings of the fMRI study of voluntary tic suppression described earlier, in which broad regions within the prefrontal cortices activated strongly during tic suppression. As children with TS meet an ever-increasing need to suppress tics in academic and social situations, their prefrontal regions would presumably be activated frequently and repeatedly, thereby inducing plastic hypertrophy of these areas. This activity-dependent hypertrophy of prefrontal regions would in turn help to decrease the severity of tic symptoms by increasing inhibitory reserve and improving the child's capacity to self-regulate tic behaviors. This interpretation of the role of the prefrontal cortex in mediating expression and severity of tics is consistent with the known role of this region in mediating tasks that require decisions of whether, when, and how to act across a time delay. An intact ability to make such decisions is needed for behavioral inhibition, working memory, and go/no go tasks (Fuster, 1989). The prefrontal cortex probably inhibits the behavioral response to the somatosensory urge to tic; it probably also determines when to release tic behaviors from voluntary suppression. Dysfunction of prefrontal regions in TS thus likely impairs an individual's capacity to inhibit tic symptoms.

An impaired ability to generate activity-dependent hypertrophy in prefrontal regions in response to a continuous need to inhibit tics should theoretically result in more severe tic symptoms. Indeed, a failure to generate this plastic response likely explains the finding of smaller prefrontal volumes in adults with TS compared to children with TS. Although tics typically improve substantially by early adulthood, the adults who participated in the previously described imaging studies had persistent, severe tics. These adults therefore represented a unique minority in the general population of individuals with a lifetime history of TS: those whose symptoms do not attenuate during adolescence.

The smaller prefrontal volumes in adults with TS probably represent a failure to induce the plastic hypertrophy of these regions in response to tics that would help to suppress them. In the absence of this compensatory plastic response, more severe tic symptoms would likely persist through adolescence and adulthood (Spessot et al., 2004).

The smaller volumes of prefrontal cortices detected in adults with TS thus likely reflect an ascertainment bias in which adults with persistent tic symptoms were recruited for the study. The significantly different findings in adults and children with TS that follow from this ascertainment bias emphasize the need to exercise caution when conducting and interpreting studies of adults with TS. They also emphasize the inherent difficulties in making inferences about the developmental trajectories and longitudinal course of TS from cross-sectional studies alone (Gerard & Peterson, 2003; Kraemer, Yesavage, Taylor, & Kupfer, 2000; Peterson, 2003).

Their shortcomings notwithstanding, MRI studies of TS thus far suggest that disturbances in the anatomy and function of the caudate nucleus may render an individual vulnerable to tics, and impaired neural regulatory systems based in the prefrontal cortex may unmask this vulnerability to tics in individuals with TS. Additional unpublished longitudinal data suggest further that caudate nucleus volumes in childhood are predictive of the persistence and severity of tics in late adolescence and early adulthood (B. S. Peterson, personal communication to A. Spessot, January 5, 2004). This finding is consistent with the hypothesis that a smaller caudate nucleus represents a trait morphological abnormality in TS that is present across all stages of the disorder. Measures of prefrontal volumes and activity within the basal ganglia during the suppression of tics correlate with the severity of tics at the time of scanning, whereas prefrontal volumes measured in childhood do not appear to predict the severity of tics in adulthood. Childhood measures of prefrontal volume, therefore, appear to be more important determinants of the severity of tics in the short term, around the time of scanning. Although prefrontal cortex volumes do not predict the severity of tics in adulthood, those who fail to generate a compensatory hypertrophic plastic response in this region seem to suffer severe tic symptoms that persist throughout adulthood.

Other brain structures have been studied in TS that are not themselves components of CSTC circuits but that are intimately related to the components of these circuits. The corpus callosum (CC), for example, has been examined in individuals with TS because it is believed to inhibit activity in prefrontal cortices through its major white matter pathways that connect the prefrontal cortices across the cere-

bral midline (Carr & Sesack, 1998). One study examining CC size in children and adults with TS compared to control subjects (Plessen et al., 2004) reported that subjects with TS had significantly smaller CC sizes than controls. CC size also correlated positively with current and worst-ever severity of tics, suggesting that smaller CCs in subjects with TS may be associated with fewer tic symptoms. Having a small CC could therefore represent a compensatory plastic response to the presence of tics, similar to a large prefrontal cortex in a child with TS. CC size correlated inversely with prefrontal cortex volumes in both the TS and control groups, although the magnitudes of these inverse correlations were significantly greater in the TS group. These results suggest that smaller CCs may contribute to or influence the growth of prefrontal cortices in all individuals, but that the normal influence of the CC on prefrontal development may be exaggerated in individuals with TS. This exaggeration presumably represents an adaptive or compensatory process in the brains of individuals with TS, given that smaller CCs and larger prefrontal cortices appear to result in less severe tic symptoms. In other words, a developmental process that happens normally in the CC may be altered and used to serve adaptive purposes in those with TS. The plastic process that produces a smaller CC may also result in a reduction of excitatory input from the CC to the GABAergic interneurons in the prefrontal cortex, thus helping to reduce inhibition of prefrontal self-regulatory control in persons with TS (Carr & Sesack, 1998; Kimura & Baughman, 1997; Krnjevic, Randic, & Straughan, 1966). This decreased inhibition of prefrontal self-regulatory functions, in turn, would facilitate the control of tic symptoms by the prefrontal cortices.

Neurotransmitters

The clinical efficacy of neuroleptic medications in the treatment of tics suggests that the midbrain dopaminergic pathways to the basal ganglia may be dysfunctional in persons with TS (Peterson & Cohen, 1998). Studies measuring levels of dopamine metabolites in cerebrospinal fluid (CSF), postmortem brain tissue, and urine of individuals with TS, however, have yielded either inconsistent results or no evidence of group differences (Anderson, Leckman, & Cohen, 1999). Ligand studies of the dopamine D2 receptor (Brooks, Turjanski, Sawle, Playford, & Lees, 1992; H. S. Singer et al., 1992; Turjanski et al., 1994; Wolf et al., 1996; Wong et al., 1997), the dopamine transporter (Albin et al., 2003; Malison et al., 1995; Meyer et al., 1999; Stamenkovic et al., 2001), and the dopamine decarboxylase system (Ernst et al., 1999) have also produced inconsistent

findings, with the few positive findings generally failing to replicate (Peterson & Thomas, 2000). These results suggest that the central synthesis and metabolism of dopamine in individuals with TS does not differ dramatically from dopamine synthesis and metabolism in healthy individuals and that perhaps dopamine systems in TS are not significantly altered.

The noradrenergic system is a major modulator of the acute response to stress in normal individuals; its dysfunction has been implicated in TS owing to the sensitivity of tic symptoms to stress (Chappell, Riddle, et al., 1994) and to the successful treatment of tics in some patients with the alpha-2 receptor agonist clonidine (Leckman et al., 1991). One study comparing levels of norepinephrine and its metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG) in the CSF of individuals with TS versus healthy controls found comparable MHPG levels in the two groups but nearly twice as much norepinephrine in the TS group compared to controls (Leckman et al., 1995). Given the shorter half-life of norepinephrine compared to MHPG, these results suggest that the basal stress response in TS is normal but that some individuals with TS may exhibit an exaggerated response to acute stress.

The well-established genetic relationship between TS and OCD suggests that a dysfunctional serotonergic system, which is believed to subserve symptoms of OCD, could also be responsible for tic symptoms. Studies of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in CSF have yielded mixed results, with one of the largest studies to date showing similar levels of 5-HIAA in the CSF of persons with TS, those with OCD, and normal controls (Leckman et al., 1995). Although preliminary studies of the postmortem brain tissue of a small sample of persons with TS have reported decreased serotonin, 5-HIAA, and the serotonin precursor tryptophan in most all cortical and subcortical regions (Anderson et al., 1992a, 1992b), these findings require replication.

In addition to the dopaminergic, noradrenergic, and serotonergic systems, other neurotransmitters that have been investigated in TS include gamma aminobutyric acid (GABA), glutamate, acetylcholine, and the endogenous opioids. Although some promising leads have been reported for all of these neurotransmitter systems, most of these studies in persons with TS have been largely equivocal. The absence of robust evidence that would identify a single pathological neurotransmitter suggests that subtle imbalances may exist among several or many transmitter systems in this condition. The involvement of several neurotransmitters is possible simply because many neurotransmitter systems function together to produce the com-

plex thoughts and behaviors associated with TS. Alternatively, a malfunction at the cellular level, including disordered second-messenger systems, abnormal proteins for vesicle release, or disturbances in the synaptic membrane, could affect the neurons of a wide variety of neurotransmitter systems and contribute to the subtle and varied disturbances in neurotransmitter levels reported in persons with TS (H. S. Singer & Wendlandt, 2001).

ELECTROPHYSIOLOGY: ELECTROENCEPHALOGRAMS AND STARTLE PARADIGMS

Early electroencephalogram (EEG) studies suggested the presence of nonspecific sharp waves and diffuse slowing in medicated individuals with TS (Bergen, Tanner, & Wilson, 1982; Krumholz, Singer, Niedermeyer, Burnite, & Harris, 1983; Volkmar et al., 1984). Other studies, however, have not detected significant differences in the EEGs of unmedicated persons with TS compared to those of normal controls (Neufeld, Berger, Chapman, & Korczyn, 1990; van Woerkom, Fortgens, van de Wetering, & Martens, 1988). Quantitative analyses of EEGs, in which the relative power contributions of each of the EEG frequency bands in specific electrode positions are compared between subjects with TS and normal controls, have similarly detected no significant abnormalities in electrical activity in the brains of persons with TS (Drake, Hietter, Bogner, & Andrews, 1992; Neufeld et al., 1990). Studies of brain stem auditory and visual evoked responses have also been equivocal (Syrigou-Papavasiliou, Verma, & LeWitt, 1988). Abnormal EEG findings in patients with TS, therefore, are thought simply to represent the effects of medication used to control tic symptoms.

One study of monozygotic twins with TS detected greater abnormalities on EEG in the twin with lower birthweight, who also typically suffered more severe tic symptoms (Hyde, Emsellem, Randolph, Rickler, & Weinberger, 1994). These findings are consistent with the hypothesis that the severity of tics may be influenced by nongenetic determinants (in this case, birthweight) that are mediated by or correlated with abnormal patterns of EEG activity (M. Hallett, 2001).

Studies attempting to classify tics as voluntary or involuntary have examined the *bereitschaft* potential, a deflection in the baseline of the EEG that precedes a self-paced, voluntary movement and that is thought to represent cortical preparation for movement (Jahanshai et al., 1995). Studies of the *bereitschaft* potential are technically challenging to

perform and have yielded inconclusive results concerning the voluntary nature of tics. One study of six patients was unable to document the presence of a *bereitschaftspotential* preceding tics (Obeso, Rothwell, & Marsden, 1981), another purported to show it in two out of five subjects (Karp, Porter, Toro, & Hallett, 1996), and yet another reported it in three TS subjects (Duggal & Nizamie, 2002). Discrepancies in the findings of these studies may be attributed to differences in the tics that were studied and to differences in patient characteristics. For example, all three patients in the third study reported premonitory urges, but these urges were not assessed in the first and largest study. Perhaps tics preceded by an urge are experienced as voluntary and have a *bereitschaftspotential*, and those not preceded by an urge could be experienced as involuntary and may not have an associated *bereitschaftspotential* as an indicator of preparation for movement.

The startle reflex is an abrupt involuntary contraction of the facial or skeletal muscles in response to a sudden sensory stimulus. An enhanced startle reflex was a feature of TS observed by Gilles de la Tourette (1885) in his original descriptions of tic disorders. More than a century later, however, studies examining the startle reflex in TS patients have produced conflicting results. In one descriptive study, 3 of 53 individuals with TS were reported to respond to an intense auditory stimulus by a blink and subsequently by a whole-body jerk that closely resembled a tic (Lees, Robertson, Trimble, & Murray, 1984). A quantitative study comparing the acoustic startle response in a small sample of persons with TS versus normal controls reported that two of the subjects with TS failed to habituate to the auditory stimulus with time, suggesting the presence of a clinically asymptomatic but exaggerated startle in some individuals with TS (Stell, Thickbroom, & Mastaglia, 1995). Another study, in contrast, showed that children with TS had startle reflexes that were similar in magnitude and habituation to those of controls. However, the automatic attenuation of the startle response immediately following a weak stimulus ("pre-pulse inhibition") was significantly impaired in these children (Swerdlow et al., 2001). These results stand in contrast to those of another study, which found no differences between subjects with TS and controls in various components of the startle response, including onset latency, amplitude, first peak latency, and habituation of the startle (Sachdev, Chee, & Aniss, 1997). Taken together, these studies suggest that the startle reflex may be abnormal in some individuals with TS but that this abnormality is relatively uncommon, often inconsequential, and possibly not more prevalent than in healthy controls.

SLEEP DISTURBANCES AND TOURETTE'S SYNDROME

Sleep disturbances, including sleep walking, sleep talking, night terrors, nightmares, difficulties falling asleep, and difficulties staying asleep, have been reported frequently in persons with TS (R. P. Allen, Singer, Brown, & Salam, 1992; Barabas & Matthews, 1985; Barabas, Matthews, & Ferrari, 1984b; Comings & Comings, 1987b; Erenberg, 1985). These sleep disturbances may be associated with more severe tic symptoms (Cohrs et al., 2001; Comings & Comings, 1987b). A number of studies have suggested that sleep disturbances in TS may be more strongly associated with co-occurring ADHD than with TS itself (R. P. Allen et al., 1992; Comings & Comings, 1987b).

Polysomnography and videotape monitoring have been used to examine sleep disturbances objectively in persons with TS, but the results of these studies have been inconsistent, probably because of small sample sizes and differing subject ages across studies (Kostanecka-Endress et al., 2003; Rothenberger et al., 2001). One recent polysomnographic study (Kostanecka-Endress et al., 2003) compared a clinical sample of TS children without ADHD to a sample of closely matched controls and found that children with TS, even in the absence of ADHD, experience a poorer quality of sleep, with particular difficulties in initiating and maintaining sleep. Further research is needed to clarify the contributions of co-occurring ADHD to sleep disturbances in persons with TS. The finding of more frequent sleep disturbances in persons with TS alone suggests that in some individuals TS is accompanied by disturbances in arousal, which is presumably mediated by the reticular activating system (Barabas, Matthews, & Ferrari, 1984a).

Polysomnographic studies of both children and adults have also detected the presence of tics during sleep in up to 80% of persons with TS (Cohrs et al., 2001; Glaze, Frost, & Jankovic, 1983; Jankovic & Rohaidy, 1987; Rothenberger et al., 2001; Silvestri et al., 1995). Although the tics that appear during sleep are similar in quality to those that appear during wakefulness, they are typically less frequent and less forceful during sleep (Cohrs et al., 2001; Fish et al., 1991). The presence of tics during sleep is evidence for the claim that tics are largely involuntary and originate in subcortical brain regions.

NEUROPSYCHOLOGY

Many children with TS have specific cognitive and learning deficits that can contribute to poor academic perfor-

mance and delayed psychosocial development. Early intervention for these children might improve their academic achievement and, in doing so, enhance their self-esteem and increase their productivity.

Early neuropsychological studies of TS were limited by small sample sizes and various other methodological difficulties. Perhaps most importantly, the majority of these studies did not account for the presence of co-occurring ADHD or OCD, each of which may carry its own profile of disturbances in neuropsychological functioning that may or may not overlap with the deficits in TS. Most recent neuropsychological studies characterize more precisely the cognitive functions of persons with TS by controlling for these co-occurring disorders.

General intellectual ability, as measured by intelligence quotient (IQ) testing, does not appear to differ in persons with TS compared with the general population (Apter et al., 1993; Bornstein, 1991). Some studies have suggested that persons with TS have lower Performance IQ (PIQ) scores than Verbal IQ (VIQ) scores, which would indicate that persons with TS experience a relative difficulty with tasks that involve visuomotor speed, visual-perceptual function, and visuomotor integration (Incagnoli & Kane, 1981; A. K. Shapiro, Shapiro, Young, & Feinberg, 1988a). Other studies, however, have attributed the discrepancy between PIQ and VIQ in persons with TS to the presence of co-occurring ADHD (Bornstein, 1990). Therefore, although it is widely accepted that those with TS tend to encounter some difficulty with nonverbal tasks, further studies are needed to clarify the contribution of ADHD to these difficulties (Como, 2001).

Approximately 22% of individuals with TS suffer from learning disabilities (Abwender et al., 1996; Erenberg, Cruse, & Rothner, 1986; Schuerholz, Baumgardner, Singer, Reiss, & Denckla, 1996), a prevalence similar to that of 15% to 20% reported in the general population (Berger, Yule, & Rutter, 1975; Pennington, 1991). The most common learning disabilities in TS may be in math and written language (Schuerholz et al., 1996), whereas reading disabilities predominate in the general population (Pennington, 1991). Co-occurring ADHD in children with TS has been reported to confer up to a fourfold greater risk for academic problems than TS in the absence of ADHD (Abwender et al., 1996; Erenberg et al., 1986; Schuerholz et al., 1996).

Other neuropsychological studies have sought to identify specific cognitive deficits in TS, focusing on tasks thought to be subserved by the basal ganglia. One of the most consistently observed cognitive deficits in TS is the impaired integration of visual and motor processes, as is

needed, for example, in copying simple and complex geometric designs (Brookshire, Butler, Ewing-Cobbs, & Fletcher, 1994; Ferrari, Matthews, & Barabas, 1984; Hagin, Beecher, Pagano, & Kreeger, 1982; Harris et al., 1995; Incagnoli & Kane, 1981; Lucas, Kauffman, & Morris, 1967; Randolph et al., 1993; Schultz, Carter, Gladstone, et al., 1998; A. K. Shapiro et al., 1988a; E. Shapiro, Shapiro, & Clarkin, 1974; Sutherland, Kolb, Schoel, Whishaw, & Davies, 1982). Similar deficits in visuomotor processing have been reported in children with ADHD, however, and most studies of individuals with TS have failed to control for co-occurring ADHD (Schultz, Carter, Scahill, & Leckman, 1998). Deficits in fine motor skills have also been reported in TS patients (Bornstein, 1990, 1991; Yeates & Bornstein, 1994), particularly when the required task depends on visual perceptual skills, as with pegboard tests. A deficit in fine motor skill may also affect one's ability to copy geometric designs effectively. Thus, the presence of deficits in fine motor skills in persons with TS may contribute to an overestimation of weaknesses in visuomotor skills because the copying tasks used to measure visuomotor performance usually require adequate fine motor skills.

In addition to impairments in visuomotor and fine motor skills, individuals with TS may have difficulty with *executive functioning* (EF), a term comprising a number of cognitive and behavioral constructs that include mental tracking, sustained attention, working memory, planning and organization, goal-directedness, cognitive flexibility during problem solving, impulse control, and self-regulation (Como, 2001). Frontostriatal circuits are thought to subserve performance on EF tasks, and thus the documented abnormalities in frontostriatal circuits in persons with TS are consistent with reported disturbances in executive functions in this same population. Studies of EF in TS have yielded inconsistent results, however, probably caused by the use of differing measures of EF across studies. Perhaps the most consistently reported EF deficit in studies of TS has been delayed reaction times in a number of testing paradigms, including the continuous performance test. Children with TS tend to perform more slowly than controls during these tests, suggesting that they may have difficulty with sustaining attention during the task (Como & Kurlan, 1991; Harris et al., 1995; Shucard, Benedict, Tekok-Kilic, & Lichter, 1997).

Variability in EF findings in persons with TS may also be explained by the presence or absence of co-occurring ADHD or OCD. Both ADHD (Barkley, 1997; Barkley, Edwards, Laneri, Fletcher, & Metevia, 2001; K. R. Murphy, Barkley, & Bush, 2001) and OCD (Head, Bolton, & Hymas,

1989; Hollander & Wong, 1996; Roth, Baribeau, Milovan, & O'Connor, 2004; Spitznagel & Suhr, 2002) alone have been associated independently with impairment in EF. One recent study of EF examined a group of children and adolescents ages 9 to 18 with TS alone, another group with TS and ADHD, and a third group with TS and OCD (Channon et al., 2003). Subjects with TS alone were impaired on only one EF measure that involved sentence completion. Subjects with TS plus ADHD, however, were impaired on three EF measures that involved sentence completion and multitasking. Subjects with TS and OCD did not differ from controls on any EF measure. These findings support further the putative role of co-occurring ADHD in the development of neuropsychological deficits in TS.

Two recent studies (Keri, Szlobodnyik, Benedek, Janka, & Gadoros, 2002; Marsh et al., 2004) have suggested that children and adults with TS have difficulties with the implicit or "unconscious" learning of skills, motor sequences, and habits, also known as *habit learning*. Studies have shown that this form of learning is mediated by CSTC circuits, particularly the dorsal striatum, in contrast to the explicit, "conscious" learning of motor behaviors and factual knowledge, termed *declarative learning*, which is subserved by structures in the mesial-temporal lobe and diencephalon (Knowlton, Mangels, & Squire, 1996; Packard & Knowlton, 2002; Squire & Kandel, 1999; Squire & Zola, 1996). In both studies, the subjects with TS who had more severe tics also displayed greater habit-learning impairment. This correlation of habit learning with the severity of tic symptoms suggests that tics may be a consequence of the degree to which striatal learning systems are dysfunctional, a possibility that is consistent with the role of the caudate nucleus in habit learning and its anatomical and functional disturbances in persons with TS. Thus, deficits in habit learning conceivably could either cause tics or influence their severity (Marsh et al., 2004).

PEER RELATIONSHIPS AND ADAPTIVE FUNCTIONING

The social, emotional, and behavioral problems that occur in TS may be just as, if not more, disruptive in day-to-day functioning as the motor and phonic tics that define the disorder. Studies have shown consistently that children with TS are at risk for social and emotional difficulties, although whether these problems are affected by the severity of tics is unclear (Bawden et al., 1998; Nolan, Sverd, Gadow, Sprafkin, & Ezor, 1996; Rosenberg, Brown, & Singer, 1995). In one study, children with TS were rated

by their peers as more withdrawn and less popular than their classmates, and they were rated by their teachers as more withdrawn and more aggressive than their peers (Stokes et al., 1991). Social difficulties in children with TS have also been reported frequently by parents (Dykens et al., 1990).

Some studies have suggested that children with TS and ADHD may have less favorable social-emotional profiles than children with TS alone. Studies using peer, parent, and self-evaluations have reported that children with TS and co-occurring ADHD tend to exhibit externalizing behavior problems such as aggression, internalizing behavior problems such as social withdrawal, and poor social adaptation. Children with TS alone, in contrast, appear to exhibit internalizing behavior problems without the additional difficulties found with co-occurring ADHD (Bawden et al., 1998; Carter et al., 2000; Spencer et al., 1998). The social withdrawal observed in children with TS alone may be a consequence of peer teasing and psychosocial stress associated with uncontrollable motor and phonic tics (Carter et al., 2000).

The families of persons with TS appear to be at risk for poor psychosocial functioning (Hubka, Fulton, Shady, Champion, & Wand, 1988; Matthews, Eustace, Grad, Pelcovitz, & Olson, 1985; Robertson, 1989). Psychosocial stress in family members can in turn increase stress in the child with TS, and stress often increases the severity of tics and other problem behaviors. Conversely, management of stress in family members can help children with TS cope with their own experience of stress. One study found, for example, that children with TS who perceived their parent's behavior as positive had more positive self-regard and less anxiety than did children with TS who had more negative perceptions of parental behavior (Edell & Motta, 1989). A follow-up study reported a significant positive association between the self-regard of children with TS and the self-regard of their mothers (Edell-Fisher & Motta, 1990).

Most reports of peer relations and adaptive functioning in persons with TS have studied clinically referred samples, thus limiting the generalizability of the findings to nonclinical populations. Nevertheless, the studies have emphasized the need for psychosocial interventions for children with TS, such as training in social skills and peer education programs in the schools that aim to reduce the stigma associated with tic disorders (Bawden et al., 1998; Carter et al., 2000). These studies have also emphasized the risks that co-occurring ADHD poses for the emotional life of children who have tics. The early diagnosis of ADHD, combined with appropriate psychosocial, educa-

tional, and treatment interventions, might reduce this emotional burden and improve the longer-term psychosocial outcomes for these children (Carter et al., 2000). Recent findings also suggest that helping parents to respond more constructively to stress may substantially benefit the emotional life of their child with tics.

TOURETTE'S SYNDROME: A MULTISTRIKE ETIOLOGY

The current conceptualization of TS is of a syndrome that develops under certain environmental circumstances in individuals who carry a specific genetic diathesis. The tic symptoms that develop may be of little or no consequence, or they may be severe enough to cause significant impairment in activities of daily life. Various conditions have been reported to co-occur with tics, such as OCD, ADHD, learning difficulties, aggressive behaviors, and sleep disturbances. These conditions, when present, appear to contribute more to functional impairment than do the tics themselves. Although some or all of the conditions that co-occur with TS may be genetically related to TS, their frequent association with TS might also be the result of a clinical ascertainment bias within individuals with TS and their families. The extent of this bias likely will be greater with co-occurring illnesses that presumably share the same neurobiological substrate with TS, such as OCD. Ascertainment bias will also be greater in families with psychopathologies that render them more intolerant of behaviors related to TS. The clinical presentation of children with TS is thus highly individualized and contextualized by myriad physiological, psychological, and social determinants.

Genetic Vulnerability

Twin and family studies suggest that genetic factors are important in determining the phenotypic expression of TS. These studies also suggest, however, that carrying the genetic diathesis to TS is neither necessary nor sufficient for producing tics or related symptoms. Carrying the putative TS genes is not necessary for producing tics because, although rare, sporadic cases of TS have been reported that presumably represent either new genetic mutations or phenocopies of TS. Carrying the TS genes is not always sufficient for producing tics because carriers do not always express the genes. As studies of monozygotic twins have shown, concordance rates for TS are high, but they are not 100%. Furthermore, the tic symptoms of monozygotic twins often differ significantly in quality and severity, sug-

gesting that environmental factors also play a role in determining the presence and severity of tics.

Because carrying the putative TS genes is neither necessary nor sufficient for producing tics and related behaviors, the concept of genetic *vulnerability* is most appropriately applied to TS. This vulnerability confers to persons carrying the genes a diathesis to tic, OCD, and likely other groups of symptoms that have yet to be identified. In most genetically vulnerable people these symptoms will be mild, if present at all. In many cases, however, various environmental determinants in combination will play a crucial role in determining an individual's clinical presentation within the spectrum of tic disorders and other semi-voluntary behaviors.

Genetic studies attempting to identify the putative TS genes have been largely unsuccessful. The search for these genes has been complicated by the wide range of phenotypic expression of the genes in quality and severity, be it expression as uncontrollable movements, as obsessions and compulsions, or as mild symptoms that are continuous with normal behavioral repertoires. When considered along with the difficulty that has been encountered in locating the putative TS genes, the continuity of tics with normal behaviors supports the possibility that these genes may not usually be expressed pathologically and that they might be present more frequently in the population than was thought previously.

Environmental Determinants

Although genetic factors are important for establishing a diathesis to TS and related disorders, environmental determinants appear to play an equally central role in determining who manifests the underlying vulnerability and the degree to which that vulnerability is expressed. These environmental determinants need to be identified before we can appreciate fully the range of phenotypic expression of the TS genes.

At present, we can only speculate about the precise contributions of individual environmental determinants to the expression of the TS phenotype. Neuroimaging studies suggest, for example, that disturbances in the structure and functioning of prefrontal cortices and other brain regions, such as the corpus callosum, may result in the inability to suppress tic behaviors. This type of disturbance might result from a failure of the prefrontal cortex to develop and organize itself properly during early childhood. It might also result from a failure of the prefrontal cortex to remodel itself in later childhood or adolescence in response to the continuous need to suppress tics in an increasingly diverse set of circumstances. Failure to establish these

compensatory responses is thought to unmask the genetic vulnerability to develop tic-related symptoms.

Compelling evidence exists suggesting that neuroendocrine factors are among the most important environmental determinants of tic expression and severity. These neuroendocrine determinants may include increased levels of sex steroids or an enhanced responsiveness of end-organs to normal levels of circulating hormones or to normal variations in the levels of these hormones. They may also include the organizational effects of sex steroid hormones on the brain during the prenatal period, which act to sensitize the brain to the activational effects of steroid hormones later in life. These neuroendocrine influences appear to predominantly confer additional risk of developing TS to females with a genetic diathesis to the disorder. By masculinizing their brain structure and function, neuroendocrine determinants increase the probability that genetically vulnerable girls will develop a neuropsychiatric disorder that typically affects boys.

Additional nongenetic determinants have been reported to increase a genetically susceptible individual's risk for developing TS, including prior infection with GABHS, perinatal complications, and stimulant medications. Psychosocial stressors appear to affect tic symptom severity in the short term, although consequences in the long term are less clear.

This model of the pathophysiology of TS comprises multiple genetic and nongenetic "strikes," each of which confers risk but none of which is sufficient for developing TS. This model is useful not only for understanding the complexities of TS, but it is probably also applicable generally to most complex neuropsychiatric disorders (Cicchetti & Rogosch, 1996). The combination of and interactions between specific risk factors and protective factors likely determine the pattern of expression, the severity, and the natural history of a neuropsychiatric disorder. Genetic and environmental influences interact in complex ways on many levels to produce a given disorder in a particular individual. This interaction is further contextualized by the individual's biologically and environmentally determined capacities to adapt and self-regulate behavior. The final individual represents a composite of his or her genetic and environmental strengths and vulnerabilities, which have been shaped and remodeled by life experiences to determine the overall set of symptoms and adaptive capacities that will be carried throughout life.

FUTURE DIRECTIONS

A thorough understanding of TS and related tic disorders requires the recognition of a specific genetic vulnerability

that, under specific environmental circumstances, may develop into a group of symptoms that includes not only tics, but also a broad array of other behavioral and emotional disturbances. Future research will aim to understand better the full range of expression of tic disorders, especially milder phenotypic variants that typically present with subtler disturbances of movement and behavior. Research will also focus on defining the genetic diathesis to tic disorders and on uncovering further the range of environmental factors that contribute to the development of these disorders. The goal of research, ultimately, is to inform preventive measures and therapeutic interventions that will influence positively the physical and emotional well-being of children, adolescents, and adults who suffer from tics and co-occurring disorders.

Among the most important sources of information about the phenomenology and natural history of tic disorders are epidemiological samples that are followed prospectively and longitudinally. By eliminating the ascertainment bias inherent in studies that use clinical samples, and by studying the same groups of individuals over an extensive period of time, prospective longitudinal studies of epidemiological samples will provide researchers with more accurate data regarding the progression of tic disorders during childhood and their gradual abatement in most people during adolescence. Longitudinal assessments will also allow for analysis of the cross-sectional and prospective associations between tic disorders and the conditions that co-occur with them. The most prominent of these conditions are OCD and ADHD, but disorders of learning, anxiety, mood, and sleep may also be present; with further study, these may become additional defining features of tic disorders. Clarification of these sometimes subtle, co-occurring conditions will be valuable, in that they are often more disruptive to the lives of individuals with tic disorders than are the tics themselves. Information obtained from prospective longitudinal studies will prove useful to those studying the developmental psychopathology of tic disorders, to those developing models for prevention of these disorders, and to those investigating modalities for treatment of the disorders. The success or failure of these measures for prevention and treatment will, in turn, help to shape further our theories regarding the etiology and pathophysiology of tics and co-occurring disturbances.

Future research will need to assess the many possible environmental factors that may influence the development and severity of tics and associated behavioral and emotional problems. Studies thus far have suggested, for example, that adverse events during the perinatal period, including maternal toxic exposures, obstetric complica-

tions, and low birth weight, may affect the development of tic disorders. The precise contributions of these events, however, to the pathophysiology of tic behaviors have yet to be elucidated. Similarly, though substantial evidence suggests that sex hormones in both the pre- and postnatal periods may predispose certain individuals to developing more severe tics, the mechanism by which hormones achieve this effect is still unknown. Again, prospective longitudinal neuroimaging studies of epidemiological samples would help to characterize further the changes in brain morphology that are driven by sex hormones and how the brains of individuals with tics may differ from normal brains with respect to sexual differentiation. Another important area that warrants further research is the possibility of an autoimmune, postinfectious etiology of tic disorders and co-occurring conditions, particularly OCD. The evidence thus far has been mixed; double-blind, controlled, longitudinal studies are still needed to clarify any relationship between infection with group A beta hemolytic streptococcus and the development or exacerbation of tics or obsessive-compulsive symptoms.

Numerous efforts to date have been aimed at identifying the genes that, in the presence of specific environmental determinants, produce symptoms of tic disorders. Results of the studies have been largely inconclusive, however, so future genetic studies will aim to replicate the relatively meager existing linkage and association data. Identification of the putative TS genes and the products of these genes will contribute to our knowledge of the neurobiochemical pathways involved in producing the TS phenotype. In the long term, this knowledge of the pathophysiology of tics will inform both measures to prevent the development of tic behaviors and measures to treat tics when they do present.

Novel strategies will be employed to identify genes associated with TS, including high-resolution, high throughput, cytogenetics techniques in individuals with TS associated with physical stigma of a clearly genetic etiology (State et al., 2003). These techniques will also be applied to the study of high-density families, including rare consanguineous pedigrees. Although such techniques are likely to identify genes that account for a small percentage of tic disorders in the general population, the approaches may help to identify underlying molecular and cellular pathways, presumably in frontostriatal systems, that produce tic disorders. Similar approaches have proved fruitful in the identification of genes and molecular pathways involved in other complex disorders, including Alzheimer's (Song & Jung, 2004; Wilquet & De Strooper, 2004) and Parkinson's (Selkoe, 2004) diseases and systemic hypertension (Lifton, Wilson, Choate, & Geller, 2002). Use of

dimensional variables derived from cognitive neuroscience studies such as quantitative trait loci (Almasy & Blangero, 1998; Amos, 1994) in genetic linkage studies will also be important directions for future research of the genetic bases of tic disorders. Similar approaches have made major advances in defining genes involved in the various components of reading pathways in persons with reading disability (Grigorenko et al., 1997; Grigorenko, Wood, Meyer, & Pauls, 2000). Combining brain imaging measures with genetic studies will help to define neurobiological subtypes of tic disorders and the influence of individual genes on specific neural pathways involved in the genesis of tic and compensatory circuits.

Neuroimaging studies of children and adults with tic disorders, particularly those using anatomical and functional MRI, have already contributed significantly to our understanding of the brain pathways that appear to malfunction in individuals with tic disorders. Specifically, the caudate nucleus has been identified as the likely location of the trait morphological abnormality in tic disorders. The frontal lobe, on the other hand, appears to be a site where the morphological changes visible on MRI represent compensatory mechanisms for tics. Differences in various other areas in the brain have also been detected in individuals with tics compared to normal subjects. The interpretation of these findings has proven difficult, however, as it is nearly impossible to distinguish whether these differences represent causes, consequences, or epiphenomena of tic disorders. Prospective, longitudinal studies of populations at risk for developing tic disorders, such as young siblings or children of individuals with tics, will be valuable for separating trait morphological differences from compensatory responses and incidental findings. Even more useful might be prospective longitudinal neuroimaging of an epidemiological sample, so that differences in brain structure between normal individuals and those who will develop tics might be captured as early as the perinatal period.

Also important in future imaging studies will be the acquisition of data from multiple imaging modalities within the same individuals. Studies will increasingly need to acquire, for example, imaging data on brain structure using anatomical MRI, function using fMRI and perfusion imaging, anatomical connectivity using diffusion tensor imaging (DTI), and brain metabolism and neurotransmitter status using magnetic resonance spectroscopy (MRS), PET, and SPECT. The power of collecting these data within the same individuals will be to correlate measures of caudate hypoplasia and frontal hypertrophy (using anatomical MRI), for instance, with measures of neuronal density (using MRS) and neurotransmitter levels (using MRS and

PET) in those regions and the axonal connectivity (using DTI) between them. These within-subject analyses will help to explain the neural systems involved in tic disorders across multiple levels of brain organization. Finally, improved postmortem studies that are under way will help to define the molecular and cellular pathways that link the vulnerability genes for tics with their manifestations in altered brain structure and function.

CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE WORK	495
REFERENCES	496

Anxiety disorders, though widely prevalent throughout development, have been relatively understudied until the past few decades. Although they are commonly perceived as less severe than other forms of psychopathology, recent research has shown that anxiety disorders are associated with a variety of adverse outcomes, including school dropout, development of other psychiatric disorders such as Major Depression, and suicide (Katzelnick et al., 2001; Pine, Cohen, Gurley, Brook, & Ma, 1998; Stein & Kean, 2000). Recent research demonstrates that the majority of adults who suffer from a mood or anxiety disorder will have developed the initial signs of their illness during childhood or adolescence, manifest as an anxiety disorder (Costello et al., 2002; Pine, Cohen, Cohen, & Brook, 1999; Pine, Cohen, & Brook, 2001; Pine et al., 1998). Anxiety disorders also exact a large financial toll on society; they are associated with sharply elevated medical costs and uti-

lization rates (Hunkeler, Spector, Fireman, Rice, & Weisner, 2003; Martin & Leslie, 2003), as well as decreased productivity at work (Dewa & Lin, 2000; Kessler & Frank, 1997). Finally, anxiety disorders are severely distressing and impairing for children (R. G. Klein & Pine, 2002; Langley, Bergman, McCracken, & Piacentini, 2004). Understanding how anxiety disorders emerge and evolve across the course of development, as well as how these disorders relate to normal manifestations of anxiety, is thus of critical importance.

For the current review of the literature on childhood anxiety disorders, we draw from a developmental psychopathology perspective that emphasizes several core tenets (Cicchetti & Cohen, 1995). Central among these is the assumption that multiple factors interact in a dynamic, transactional fashion to affect how a disorder emerges. Not only may a given etiological factor produce any of several different effects depending on the system or context in which it operates (principle of multifinality), but a wide range of factors may lead to similar outcomes (principle of equifinality). Thus, the appearance of an anxiety disorder at a given point in development depends on the evolving inter-

Section on Development and Affective Neuroscience, Mood and Anxiety Disorders Program, National Institute of Mental Health, National Institutes of Health, Department of Health and Human Services.

play among vulnerabilities and protective factors for a particular child.

The developmental psychopathology perspective also assumes that normal and deviant development must be studied in concert. This assumption is predicated on the idea that an accurate understanding of dysfunction necessitates a comparable understanding of normal or successfully adaptive developmental paths. Anxiety, for instance, is an integral part of human existence throughout the life span; only under some circumstances does it manifest in a dysfunctional way. It is therefore critical to describe normative experiences of anxiety if pathological manifestations are to be identified and studied.

An additional core tenet of the developmental psychopathology perspective informing this chapter is that the role of development must be considered in the emergence of a disorder. Symptoms vary in their meaning and import at different points in development. Fear of separation from a parent, for instance, is normative in a toddler but potentially pathological in an older child.

This review of recent perspectives on childhood anxiety disorders is divided into three sections. First, we define relevant terms and review available literature on classification of childhood anxiety disorders. Specifically, we examine data regarding commonalities and differences among the anxiety disorders as they present in juveniles and in adults. In the second section, we review in more detail the data on one childhood anxiety disorder: Social Phobia or Social Anxiety Disorder. Available data on longitudinal outcome, family history, and treatment suggest clear distinctions among the anxiety disorders, with Social Anxiety Disorder, Posttraumatic Stress Disorder (PTSD), and Obsessive-Compulsive Disorder (OCD) showing discrete profiles. Full examination of each of these disorders, however, is beyond the scope of this chapter. We focus specifically on Social Anxiety Disorder due to the fact that research on this disorder has increased recently from clinical psychopathology, cognitive neuroscience, and developmental psychology perspectives. Social Anxiety Disorder therefore provides an excellent model for integrating these viewpoints, especially insofar as they have each grappled with the constructs of emotion and emotion regulation. Third, we summarize recent advances in basic neuroscience that relate to Social Anxiety Disorder and emotion regulation. Much like research in developmental psychology and psychopathology, these advances in neuroscience suggest that fear states might be best conceptualized as a family of distinct but related entities. Evidence regarding both shared and discrete aspects of various fear states is reviewed.

DEFINITION OF TERMS

Our aim is to integrate recent insights from several related but diverse fields, including developmental psychology, psychiatry, cognitive neuroscience, and epidemiology, under the rubric of developmental psychopathology. Such an integrative effort is destined to fail before it begins unless a common terminology is established that bridges all of the disciplines of interest. Hence, we begin by clarifying terms. We recognize that building a common lexicon requires simplifying key concepts in ways that may obscure nuances recognized in one field or another. However, in the interest of uniting multiple disciplines, we consider it more important to establish a common core language than to elucidate subtle differences.

We use the term *emotion* to refer to a brain state associated with a reward or a punishment. Changes in such brain states necessarily are reflected both in measures of neurophysiology and in measures of information processing; they can be, but do not have to be, reflected in measures of subjectively reported experience. As a result, we use *emotion* to apply to reward- or punishment-linked brain states and associated patterns of physiological response or information processing. We do not use the term to describe subjective experience. The term *reward* refers to any stimulus that an animal or a human will extend effort to procure, whereas the term *punishment* refers to any stimulus that an animal or human will extend effort to avoid (Rolls, 1999).

Consistent with Damasio (2001; Damasio et al., 2000), we use the terms *feeling* and *emotion* to refer to different constructs. We restrict our use *feeling* to the subjectively experienced, reliably describable state associated with the occurrence of an emotion. Changes in feelings represent core aspects of psychiatric disorders as they are currently conceptualized in the standard nosology of the *Diagnostic and Statistical Manual of Mental Disorders (DSM)*. Many diagnostic criteria rest on subjectively reported changes in emotional states or behaviors; very few rely on objective measures of behavior; none rely on direct measures of changes in brain states.

This focus on feelings in current understandings of most psychiatric diagnoses makes it difficult to conduct translational work that integrates research across human and nonhuman species in an effort to better understand mental disorders. In particular, subjectively experienced states are central to our definition of feeling. Yet, the degree to which various nonhuman organisms experience feelings is unclear, even though there is striking continuity among many mammalian species in terms of experienced emotion (Davis & Whalen, 2001; LeDoux, 1994, 1998, 2000).

Therefore, truly translational studies must grapple with the interface between feelings and emotions, an interface that remains imprecisely specified across species.

In addition to distinguishing between emotions and feelings, we consider fear and anxiety to represent different constructs. The term *fear* refers to both the emotion and the feeling state that humans experience when they directly encounter stimuli that they perceive as threatening or as capable of producing harm and that elicit avoidance. Like fear, the term *anxiety* applies to both an emotion and a feeling state experienced by humans. The two constructs involve similar changes in behavior, cognition, and physiology but unlike fear, anxiety occurs in the absence of overt threat or punishment. As defined, anxiety does not necessarily connote a pathological state. We discuss the distinction between *normal* and *pathological* anxiety states when we review childhood anxiety disorders and their classification.

The current chapter discusses anxiety in the context of research on emotion regulation, a construct that requires precise and careful definition. The term *emotion regulation* has been used to describe diverse clinical and psychological phenomena. Consistent with Thompson (1994, pp. 27–28), we adopt a narrow definition, restricting our use of the term to describe “processes responsible for monitoring, evaluating, and modifying emotional reactions . . . to accomplish one’s goals.” Given our emphasis on the distinction between emotions and feelings, perhaps a parallel focus on feeling regulation is warranted. For the sake of simplicity, our use of *emotion regulation* encompasses both processes that regulate emotions and processes that regulate feelings, as the two are inextricably linked.

When applied to research on anxiety, this narrow definition of emotion regulation inherently encompasses two related constructs. The first consists of the stimuli and circumstances that can elicit fear and/or anxiety. The second consists of the behavioral, cognitive, and neural processes that are engaged in the service of monitoring, evaluating, and modifying the emotional reaction of fear or anxiety that a stimulus elicits. In many areas of developmental psychopathology, mental disorders have been conceptualized as disorders of emotion regulation. Using our definitions, this view would suggest that pathology lies less in the circumstances that elicit emotion or the magnitude of an initial emotional reaction and more in the degree to which processes can be engaged to regulate this reaction once it emerges.

Davidson (1998) provides a complementary view to this perspective on emotion regulation with a model that emphasizes “affective chronometry,” or the temporal dynamics involved in the processing of emotionally evocative

stimuli. In particular, he distinguishes between processes engaged as an affective reaction rises to its peak and processes engaged as the reaction subsides. According to this perspective, it may be arbitrary to make conceptual distinctions between emotional reactions and emotional regulation. Instead, these two constructs may represent temporally distinct phases in an individual’s response to an emotional stimulus. Different forms of pathology, Davidson suggests, may thus relate to different patterns of disruption in the temporal sequence of emotional responding. Whereas some disorders may relate to perturbations that occur early in the course of a response, others may relate to perturbations that are evident later, during the processing of emotional stimuli.

Different theoretical perspectives provide various hypotheses linking abnormalities in either emotional reactions or emotion regulation, as they are measured in the laboratory, to developmental psychopathologies. As of this writing, these remain novel, but largely untested, hypotheses. This caveat applies, in particular, to current research on anxiety disorders.

CLASSIFICATION OF CHILDHOOD ANXIETY DISORDERS

The fourth edition of the *DSM* (*DSM-IV*; American Psychiatric Association, 1994) recognizes nine distinct anxiety disorders: Separation Anxiety Disorder (SAD), Social Phobia, Generalized Anxiety Disorder (GAD), Specific Phobia, PTSD, Acute Stress Disorder, Panic Disorder, and OCD. These anxiety disorders, with the exception of SAD, are all diagnosed using similar criteria for children, adolescents, and adults. By definition, SAD must begin before adulthood according to *DSM-IV*. In addition, fewer symptoms must be evident in juveniles than in adults to meet criteria for GAD. The strong parallels in diagnostic criteria for individuals at different developmental stages in *DSM-IV* represent a change from earlier versions of the *DSM*. This change reflects the *DSM-IV* nosological convention of using identical diagnostic criteria across development unless there are strong data that support using an alternative scheme.

For each of the nine anxiety disorders, as with virtually all other mental conditions in *DSM-IV*, individuals must exhibit a specific set of symptoms and show signs of either impairment or “significant distress.” The latter requirement has been called the “impairment/distress” criterion. Beginning with revisions in *DSM-III* in 1980 (American Psychiatric Association, 1980), recent conceptualizations

of mental illnesses have increasingly emphasized such impairment or distress criteria to differentiate normal fluctuations in psychiatric symptoms from categorically distinct disorders. At the conceptual level, the impairment/distress criteria facilitate relatively clear distinctions between normal and abnormal levels of symptomatology. However, in practice, it is easier to distinguish normal from abnormal levels of symptoms in some conditions than in others. For example, some conditions, such as pervasive developmental disorders and psychosis, typically present with intense or severe symptoms, such as frank delusions, that are rarely seen as normal in any context. Such conditions are also usually associated with marked impairment. Distinguishing these conditions from normality is therefore relatively easy. In contrast, distinguishing normal but slightly elevated levels of anxiety from an anxiety disorder can be difficult, particularly in the absence of specific functional impairment criteria (Beidel, Silverman, & Hammond-Laurence, 1996). This difficulty is compounded by the fact that diagnostic decisions in anxiety disorders must often be made against the background of normative developmental changes in behavior. For example, marked distress associated with separation from a parent might be considered normal in a preschooler but abnormal in a child only a few years older. The developmental psychopathology perspective's emphasis on considering normal and deviant processes in conjunction is thus particularly appropriate to the study of anxiety disorders.

The subtlety of the distress/impairment threshold for anxiety disorders complicates not only the identification of pathology in individuals, but also the determination of population-level prevalence rates. Studies that set different impairment thresholds tend to find dramatically different prevalence rates for anxiety disorders. In contrast, the threshold for impairment has a much smaller influence on rates for other psychiatric conditions, such as depression and Conduct Disorder (Costello, Mustillo, Erkanli, Keeler, & Angold, 2003; Shaffer et al., 1996).

The challenges associated with differentiating normal from abnormal anxiety illustrate a basic problem with current methods for diagnosing mental disorders. Namely, identification and categorization of most psychopathology depends exclusively on clinical evaluation. Alternative, more objective approaches, such as assessments of physiology, genetics, or brain function, are used only for the diagnosis of mental disorders that result from underlying nonpsychiatric medical illnesses. In light of this limited method of diagnosis, current definitions of most mental disorders must be regarded as preliminary. As knowledge of pathophysiology advances, the criteria we use to distin-

guish health from disease and normal from abnormal anxiety may change. Moreover, some psychiatric conditions, including certain anxiety disorders, may eventually be recognized as extremes on continua with normality, just as some forms of hypertension are thought to represent the extreme end of the blood pressure continuum. In contrast, other psychiatric conditions such as the psychoses, may come to be recognized as categorically distinct from normality, just as a fractured bone differs categorically from a healthy bone.

The nine anxiety disorders in *DSM-IV* are broadly related, in that anxiety symptoms of some sort constitute their central features. However, they do not form a neatly unified group. In general, five sets of standards have been used to distinguish among the anxiety disorders, although relatively few data are available that use these criteria to validate specific anxiety disorders in children and adolescents. First, *DSM-IV* defines these conditions as distinct by setting forth different sets of diagnostic criteria for each disorder. These criterion sets identify symptoms that most frequently cluster in patients with one or another condition. Second, the specific longitudinal trajectory and associated pattern of comorbidity for each anxiety disorder mark the individual conditions as distinct. Third, studies delineate unique patterns of aggregation within families for different anxiety disorders and associated conditions. Fourth, distinct anxiety disorders have been associated with specific risk factors or perturbations in biological systems reflective of underlying pathophysiology. Finally, for some adult anxiety disorders, treatment studies identify unique response patterns to psychotherapeutic or psychopharmacologic interventions. Table 12.1 summarizes some of the key factors from this perspective that distinguish among the anxiety disorders.

Within the pediatric anxiety disorders, probably the strongest evidence for specificity derives from studies of OCD, which is characterized by recurrent, time-consuming, and impairing compulsions and/or obsessions. With respect to longitudinal trajectory and associated comorbidity, OCD exhibits relatively strong cross-sectional and longitudinal associations with disorders of impulse control, including tic disorders and Attention-Deficit/Hyperactivity Disorder (ADHD; Grados et al., 2001; Peterson, Pine, Cohen, & Brook, 2001). Similarly, OCD that occurs early in development predicts an increased risk for OCD either later in adolescence or during adulthood (Peterson et al., 2001). Family-genetic studies show similar patterns of co-aggregation, with associations among OCD, tics, and ADHD emerging frequently within families (Pauls, Albro, Goodman, Rasmussen, & Leckman, 1995; Pauls,

TABLE 12.1 Distinctions among the Anxiety Disorders

	OCD ^a	PTSD ^b	Social Anxiety Disorder	Separation Anxiety Disorder/(Panic)	GAD ^c
Symptoms	Obsessions and/or compulsions	Reexperiencing, arousal, and avoidance associated with trauma	Anxiety in social or performance situations	Anxiety regarding separation from attachment figures	Persistent anxiety and worry across multiple areas
Course/comorbidity	Associated with ADHD ^d and tic disorders	Associated with a wide range of disorders (MDD, ^e disruptive behavior disorders, etc.)	Relatively restricted comorbidity and risk profile	Associated with Panic Disorder	Associated with MDD ^e and a range of anxiety disorders
Familiarity	Associated with ADHD ^d and tic disorders	Associated with a wide range of disorders (MDD, ^e disruptive behavior disorders, etc.)	Relatively restricted comorbidity and risk profile	Associated with Panic Disorder and MDD ^e	Associated with MDD ^e
Biology	Basal ganglia dysfunction	HPA ^f axis dysfunction	Possible amygdala dysfunction in the context of socially threatening stimuli	Respiratory dysfunction	?
Treatment	SSRI ^g	SSRI ^g	MAOI, ^h SSRI ^g	TCA, ⁱ SSRI, ^g MAOI ^h	TCA, ⁱ SSRI, ^g MAOI ^h

Notes: ^aObsessive-Compulsive Disorder, ^bPosttraumatic Stress Disorder, ^cGeneralized Anxiety Disorder, ^dAttention-Deficit/Hyperactivity Disorder, ^eMajor Depressive Disorder, ^fhypothalamic-pituitary-adrenal, ^gselective serotonin reuptake inhibitor, ^hmonamine oxidase inhibitor, ⁱtricyclic antidepressant.

Leckman, Towbin, Zahner, & Cohen, 1986; Peterson et al., 2001). Such patterns of comorbidity are thought to reflect dysfunction in a common neural circuit encompassing the prefrontal cortex, striatum, and thalamus, forming so-called cortico-striato-thalamo-cortical (CSTC) loops. In some cases, the associations among OCD, tics, and ADHD have been related to streptococcal infection (Swedo et al., 1998), which is thought to disrupt functional aspects of CSTC circuitry. In general, these findings on comorbidity patterns, familial aggregation, and pathophysiology are specific to OCD and related conditions, distinguishing them from other anxiety disorders.

Although the evidence of specificity is not as strong as in OCD, relatively consistent findings also differentiate PTSD and Acute Stress Disorder (ASD) from other anxiety disorders. First, both conditions are unique in the *DSM*, in that a specific causal factor, in the form of a frightening event or stressor, is explicitly tied to the onset of both disorders. The pattern of associated symptoms and comorbidities is also distinctive in PTSD, in that they are highly influenced by the context of the stressor. For example, PTSD can develop following an isolated traumatic event that occurs against a background of relatively low stress, or it may develop following a prolonged period of multiple stressors and traumas. Not only are these conditions associated with high levels of anxiety, arousal, and avoidance, but they also typically involve reexperiencing and dissociation symptoms that are not associated with other anxiety disorders. This has led to some debate as to whether the

conditions might be better conceptualized as dissociative disorders, mood disorders, or in their own category as stress-related disorders (Brett, 1997; G. M. Sullivan & Gorman, 2002).

Patterns of comorbidity also tend to differ between traumatized children, who often exhibit signs of dysfunction in multiple domains, and children with other anxiety disorders, whose dysfunction is relatively circumscribed. Not only do traumatized children show symptoms of PTSD or ASD, but they also frequently exhibit symptoms of *DSM-IV* behavior disorders and mood disorders (Ackerman, Newton, McPherson, Jones, & Dykman, 1998).

Relatively few studies examine longitudinal outcomes or familial aggregation in childhood PTSD. Nevertheless, some data do demonstrate associations between PTSD in children and signs of stress-related psychopathology in their parents (Yehuda, Halligan, & Bierer, 2001; Yehuda, Halligan, & Grossman, 2001). Similarly, relatively few studies differentiate aspects of risk or pathophysiology associated with PTSD from those found in other anxiety states that arise following trauma. Nevertheless, particularly in adults, evidence suggests that PTSD is characterized by a specific pattern of dysfunction in the hypothalamic-pituitary-adrenal axis and associated neural structures, including the hippocampus and amygdala (Bremner, Narayan, et al., 1999; Bremner, Staib, et al., 1999; Yehuda, 2001, 2002). In general, data distinguishing childhood PTSD from other childhood conditions have been weaker than those in adult PTSD, though some

findings are consistent in children and adults (Pine, 2003). Finally, optimal psychotherapeutic treatment of PTSD also differs from that for other anxiety disorders, in that it often involves a heavy focus on traumatic events (J. A. Cohen, 2003).

Investigators have adopted conflicting conceptualizations of SAD during the past few decades. For many years, this condition has been viewed as strongly related to Panic Disorder. Panic Disorder is characterized by sudden, unexpected paroxysms of extreme anxiety or terror. Although panic attacks can occur at any point during the life span, the onset of spontaneous, recurrent panic attacks rarely occurs before adolescence. In severe cases, the disorder typically follows a developmental course in which isolated, spontaneous panic attacks begin during adolescence and are followed later in life by multiple, recurrent panic attacks that meet criteria for Panic Disorder (R. G. Klein & Pine, 2002; Pine, 1999; Pine et al., 1998). Agoraphobia, or anxiety about being in places or circumstances from which escape would be difficult or embarrassing in the case of a panic attack, is a common ensuing complication. The conceptualization of SAD as related to Panic Disorder derives largely from clinical data in adults with Panic Disorder, who report high rates of SAD during childhood (Bandelow et al., 2001; Silove et al., 1995). Such data are vulnerable to various types of biases, including referral biases and retrospective distortions. In general, data from family and longitudinal studies provide some support for the view that SAD relates to Panic Disorder; however, the data are not especially compelling (R. G. Klein & Pine, 2002; Pine, 1999; Pine et al., 1998). Much more supportive findings have emerged, however, in studies of respiratory function, where both panic attacks and SAD have been linked to similar perturbations in respiration (Goodwin & Pine, 2002; Johnson et al., 2000; Pine, Klein, et al., 2000). An alternative conceptualization of SAD identifies the disorder as a non-specific response to various forms of distress. Consistent with this perspective, high rates of SAD are found in offspring of parents with Major Depression (Biederman, Faraone, et al., 2001), in individuals who have experienced traumatic stress (Goenjian et al., 1995; Pine & Cohen, 2002), and even in the context of streptococcal infection (Swedo et al., 1998).

Finally, Generalized Anxiety Disorder is characterized by a recurrent pattern of worries and anxiety about a range of topics. Although comorbidity is high for all pediatric anxiety disorders, GAD virtually always presents with another concurrent anxiety disorder (R. G. Klein & Pine, 2002; Research Unit on Pediatric Psychopharmacology [RUPP], 2001). This has led to considerable debate about

the validity of the diagnosis, with some contending that GAD represents a complicating factor in other anxiety disorders rather than an independent disorder (R. G. Klein & Pine, 2002).

The diagnosis of GAD changed with the revision to *DSM-IV*. Prior to this revision, children who presented with a pattern of recurrent worries were diagnosed with Over-anxious Disorder and adults with similar symptoms were diagnosed with GAD. However, with the publication of *DSM-IV*, the GAD diagnosis subsumed Overanxious Disorder so that age could be eliminated as a defining diagnostic criterion (Shaffer, 1996). Some debate continues concerning the advisability of this change, reflecting the fact that relatively weak data are available to support either position. Perhaps the way GAD differs most from other anxiety disorders is in the strength of its relationship with Major Depressive Disorder (MDD). Most anxiety disorders, including OCD, PTSD, and Panic Disorder, show strong associations with MDD. However, in children as well as adults, GAD is particularly tightly linked with MDD. Evidence for this close relationship emerges both in family genetic research (Breslau, Davis, & Prabucki, 1987; Kendler, 2001; Silberg, Rutter, & Eaves, 2001) and in longitudinal studies (Pine et al., 1998).

Taken together, evidence identifying unique patterns of symptoms and familial aggregation patterns, as well as markers of neurophysiological dysfunction, supports the view that anxiety disorders can be defined as a family of related but distinct conditions. However, for some disorders, the evidence of commonalities is almost as strong as the evidence of specificity. For example, common to virtually all of the anxiety disorders is a persistent tendency to experience any of a wide range of anxious symptoms, which can be somatic (e.g., racing heart, sweating, nausea, trembling), cognitive (e.g., worry, fear), or behavioral (e.g., avoidance, tearfulness). These symptoms may occur discretely or in clusters; when four or more somatic or cognitive symptoms suddenly co-occur and rapidly peak in the context of intense fear, they constitute a panic attack. As noted earlier, in individuals with Panic Disorder, panic attacks occur spontaneously and without apparent provocation, sometimes leading to agoraphobia, or a fear of experiencing panic symptoms or attacks in a public setting. However, individuals with other anxiety disorders also experience panic attacks, which are cued by specific feared stressors. For example, individuals with Social Anxiety Disorder may experience panic when confronted with particular social cues. Children with SAD may experience panic when leaving for school in the morning. Worry also represents a core feature of most anxiety states. In GAD,

worry and excessive anxiety develop about a variety of events or circumstances. Objects of worry may also be circumscribed objects or situations, as in Specific Phobia, SAD, or Social Phobia. Symptom patterns vary relatively little across the phobias and GAD; consequently, these disorders are differentiated primarily on the basis of the environmental cues that precipitate anxious reactions.

The present chapter focuses on one type of anxiety disorder, Social Phobia, which has also been termed Social Anxiety Disorder. The recent shift from the term Social Phobia to the term Social Anxiety Disorder is based on evidence that Social Anxiety Disorder differs dramatically from specific phobias in several ways. These differences are apparent on measures of impairment, treatment-seeking behavior, longitudinal outcome, and familial aggregation (Fyer, 1998; Fyer, Mannuzza, Chapman, Martin, & Klein, 1995; Pine et al., 1998). Unlike the various forms of Specific Phobia, which are each associated with low rates of impairment and high rates of familial aggregation, Social Anxiety Disorder is associated with relatively high rates of impairment (Fyer, 1998). Moreover, familial aggregation data suggest that Social Anxiety Disorder should not be considered a subcategory of the larger family of phobias (Fyer et al., 1995).

In individuals with Social Anxiety Disorder, anticipation of embarrassment in social or performance situations is the primary trigger for anxiety symptoms. *DSM-IV* recognizes two forms of Social Anxiety Disorder: One form is narrow and specific and is characterized by an isolated fear of public speaking; the other is more generalized and is characterized by high levels of anxiety in a range of social situations. Virtually all studies examining commonalities and differences between the specific and generalized forms of Social Anxiety Disorder have focused on adults (Fyer, 1993; Kendler, 2001; Mannuzza et al., 1995; Schneier, Spitzer, Gibbon, Fyer, & Liebowitz, 1991). This body of research provides emergent support for *DSM-IV*'s assertion that the two types of Social Anxiety Disorder are distinct. Specifically, the generalized type of Social Anxiety Disorder is associated with more impairment and more extensive comorbidity than is the specific type (R. G. Klein & Pine, 2002; Schneier et al., 1991). This pattern of findings has led to a greater focus in therapeutic and developmental studies on the generalized type.

Prior to *DSM-IV*, children with severe avoidance of social situations could be diagnosed with Avoidant Disorder of Childhood instead of Social Phobia. In the revisions leading to the publication of *DSM-IV*, Social Anxiety Disorder subsumed Avoidant Disorder of Childhood, just as GAD subsumed Overanxious Disorder of Childhood. This change

reflected the fact that the distinction between Avoidant Disorder and Social Phobia appeared relatively arbitrary in clinical practice and epidemiological settings. Not only did this change eliminate age as a diagnostic criterion, but it also decreased redundancy among diagnoses, given that Avoidant Disorder appeared to be a rare condition that overlapped considerably with Social Anxiety Disorder.

Selective mutism, a condition characterized by a consistent failure to speak in social situations, also shows some overlap with Social Anxiety Disorder. Although anxiety symptoms are not among the diagnostic criteria for selective mutism, a large proportion of children with selective mutism endorse marked social anxiety (Bergman, Piacentini, & McCracken, 2002), and a substantial number also meet criteria for Social Anxiety Disorder (R. G. Klein & Pine, 2002). Though some controversy remains, current consensus suggests that at least some subgroups of children with selective mutism are likely to suffer from a condition with a strong pathophysiologic resemblance to Social Anxiety Disorder (R. G. Klein & Pine, 2002).

In general, data differentiating Social Anxiety Disorder from other anxiety disorders and related conditions are relatively strong. We review these data in detail. Briefly stated, however, the available evidence suggests that the disorder can be differentiated from other anxiety states on the basis of symptoms, longitudinal outcome, familial aggregation, and pathophysiology. In fact, the data on specificity in childhood Social Anxiety Disorder are as strong as or stronger than those for any other anxiety disorder except OCD. A focus on Social Anxiety Disorder is also warranted in light of recent findings in developmental psychology and cognitive neuroscience research. These findings provide novel insights concerning behavioral, cognitive, and neural aspects of social relationships, particularly where such relationships involve perturbations in emotion. This natural intersection offers an unusual opportunity to bridge recent research on clinical psychopathology, which focuses on social anxiety per se, and recent research on broader aspects of social relationships and emotion regulation.

HISTORICAL PERSPECTIVE

If the published record is an accurate indication, anxiety among children and adolescents has been of limited interest to clinicians and researchers throughout much of history. In their carefully researched historical overview of youth anxiety, Treffers and Silverman (2001) found few published references to anxiety in children before the early

nineteenth century. Indeed, between the fourth century B.C., when Hippocrates (460–370 B.C./1886) cited “fears” as one of the illnesses of infants, and the past 200 years, the literature on youth anxiety is remarkably sparse.

When pediatric anxiety was addressed in early medical writings, specific fears and nightmares were frequently the focus. Several medieval and Renaissance medical pamphlets suggested cures for these problems, which were thought to stem from imbalanced humors or digestive upsets. The English physician Robert Pemell (1653/2000), for instance, recommended keeping the child on a “moderate diet” and administering laxatives to “take away the corrupt humours in the stomach.” Others, such as Marcin of Urzedow, a Polish herbalist, suggested dill as an effective treatment for nightmares (Knab, 1995).

Historical considerations of anxiety in children, as well as in adults, reflect the tension inherent in current conceptualizations between a focus on specific anxiety symptoms and broad categories of anxiety states. Writings over the past centuries recognize anxiety surrounding social interactions as one specific form of anxiety state. Darwin (1998), for example, noted cross-species parallels in the manifestations of anxiety when encountering threatening conspecifics. Nevertheless, the degree to which such anxiety has been considered distinct from other fears remains unclear. Social anxiety per se received little attention in medieval medical treatises, although Treffers and Silverman (2001) mention a notable exception in which the Italian doctor Girolamo Mercuriale cited fear as a contributing factor to children’s stammering in his tract “De Morbis Puerorum.” Social anxiety, like separation anxiety, was instead more commonly discussed in educational materials. Some of the earliest specific references to childhood anxiety about social interaction, for example, appeared in advice and etiquette manuals or “books of nurture” during the Middle Ages, which contained instructive aphorisms and verses on a wide range of problems, including timidity or shyness and school refusal (Wardle, 1991).

By the mid-nineteenth century, discussions of social anxiety began to appear in the medical literature (Pelissolo & Lepine, 1995), with an initial focus on phobic fears of blushing, or erythrophobia. Although these reports typically centered on adult patients, it was not unusual for their symptoms to date back to adolescence. In one of the earliest case studies, the German physician Johann Ludwig Casper (1846) described a 21-year-old medical student who had suffered from a severe fear of blushing since the age of 13. Tormented by this phobia, which left him unable to bear even the company of his best friend, he became increasingly depressed and ultimately committed suicide.

Pitres and Régis (1897) described two adult brothers whose fears of blushing could be traced back to puberty.

A number of comparable cases were reported around the turn of the twentieth century, and increasingly, they were grouped with cases of more broadly conceptualized social anxiety (Pitres & Régis, 1897). In his taxonomy of phobias, Pierre Janet (1903, p. 210) classified erythrophobia among the “phobies sociales” or “phobies de la société,” a specialized type of situational phobia that also included such diverse and specific problems as phobias about marriage, teaching schoolchildren, and supervising a domestic staff. The French psychiatrist Paul Hartenberg (1901, p. 201) similarly grouped erythrophobia with “maladies de la timidité,” or disorders of shyness. For Hartenberg, such disorders stemmed from a combination of fear, particularly fear of humiliation or of being perceived as inferior, and shame. As Fairbrother (2002) has noted, Hartenberg’s conceptualization of socially oriented anxiety was remarkably similar to the *DSM-IV* definition of Social Phobia, particularly in its emphasis on fear of negative evaluation as a cardinal symptom. Hartenberg was also one of the few clinicians of his time to discuss social anxiety as a problem that affected children as well as adults. However, he believed that until puberty, children were unlikely to perceive their shyness or timidity as a problem that needed to be addressed.

Although the phenomenology of Social Phobia was well-documented during the late nineteenth century, clinicians struggled to understand the disorder’s etiology. In Casper’s (1846, p. 286) case study, for instance, he expressed bafflement about what had caused his patient’s distress, musing at one point about whether it could have been a “punishment from God” or a “consequence of original sin.” Patients themselves attributed their social anxieties to a variety of causes during the second half of the century. In his list of patients’ explanations for their social fears, Hartenberg (1901, pp. 134–135) included “anemia,” “lack of air,” “my state of nervous weakness,” “modesty,” “fear of ridicule,” “my detestable education,” “lack of money,” and “awkwardness.”

As case observations accumulated, clinicians began to piece together more plausible hypotheses about etiology, and by the turn of the century, ascendant theories closely resembled those that are currently favored. Several clinicians, including Hartenberg (1901) and the Swiss psychologist Edouard Claparède (1902), noted that multiple members of the same family often exhibited problems with social anxiety. As a consequence, these clinicians agreed that the disorder must have a hereditary component. Additionally, Hartenberg implicated environmental factors in

the disorder, listing a variety of situations and social stimuli that tend to elicit anxiety from those who are genetically vulnerable.

There was little consensus at the turn of the twentieth century regarding optimal treatments for pathological social anxiety. Adult case reports described a number of treatments that practitioners implemented with varying degrees of success. These therapies included hypnosis, psychotherapy, opium, bromides, and, for erythrophobia, bleeding with leeches (Pitres & Régis, 1897). For children, Hartenberg (1901) presciently suggested using strategies that closely resembled graduated exposure to decrease fears of speaking in class or social interaction. He also advocated structuring children's experiences at school in ways that would prevent social anxiety. By helping children to be less emotional, strengthening their self-confidence, and habituating them to interactions with strangers, schools played an important role in steering children from future nervous problems.

As the twentieth century progressed, psychodynamic and strict behaviorist theories of anxiety became prominent. Although they varied considerably in their interpretations of maladaptive or neurotic anxiety, the psychodynamic theorists were loosely united by two beliefs about the construct. First, there was consensus that it stemmed from unconscious, internal conflicts related to early patterns of interaction between an individual and his or her parents, especially the mother (see May, 1950, for a review). Harry Stack Sullivan (1953), the most interpersonally oriented of the psychodynamic theorists, went so far as to assert that all anxiety arose from early apprehension about disapproval from significant others. Second, the vulnerability to experience neurotic anxiety was thought to be inherited. In contrast, behaviorists such as John Broadus Watson (1929) held that maladaptive emotional reactions such as anxiety constituted patterns of behavior that stemmed largely from conditioning experiences. According to Watson, negative or aversive conditioning events were especially likely to lead to maladaptive behavior if they occurred in infancy or childhood, because habits were typically acquired and modified during those periods.

Given the primacy of psychodynamic theory in medical circles during much of the early twentieth century, it is not surprising that social anxiety in youth was again addressed largely in educational contexts (e.g., Dealy, 1923; Goodenough, 1929; Uger, 1938). Teachers and parents were encouraged to help shy or timid children become more outgoing and confident, and, in a few cases, psychotherapeutic approaches were applied to increase such children's comfort in social interactions (e.g., Solomon & Axelrod, 1944).

Although research interest in adult social anxiety increased steadily during the last half of the twentieth century (e.g., Cheek & Buss, 1981; D. Watson & Friend, 1969), it was not until the 1980s that social anxiety among children and adolescents became a prominent focus of study (Pine, 1999). Indeed, as recently as 1966, the typical age of onset for Social Phobia was thought to be 19 years (Marks & Gelder, 1966), thus, largely precluding the need to examine the disorder in younger individuals.

Research that accumulated in the second half of the twentieth century led to a gradual erosion of the view that social anxiety or fear of conspecifics could be lumped together with the larger family of neurotic states or fears associated either with internal conflicts or with exposures to conditioning experiences. Increasingly, specific anxiety states were recognized as distinct conditions. Current conceptualizations of anxiety disorders were largely shaped by three major sets of research findings from the last half of the twentieth century. One of these sets of findings emerged largely from research in adults, a second from research in children and adolescents, the third from research in the neurosciences. We briefly review findings in clinical research that stimulated this changing perspective; findings in basic research are reviewed in a later section of the chapter.

Late twentieth-century developments in adult clinical psychopharmacology greatly influenced modern conceptualizations of anxiety disorders in general and Social Anxiety Disorder in particular. One of the most important advances derived from D. F. Klein's (1964) observation that adults with spontaneous panic attacks showed a distinctive clinical response to the tricyclic antidepressant (TCA) imipramine. This finding led him to suggest that unique responses to specific pharmacological agents may characterize specific anxiety states. Although specifics of Klein's initial argument are still debated, his broader position on the utility of so-called "pharmacological dissection" is widely accepted.

Large-scale pharmacological studies during the 1990s have provided further support for the view that anxiety states are a family of distinct but related conditions. Probably the strongest evidence of specificity comes from recent clinical pharmacology research on adult Social Anxiety Disorder and OCD. Social Anxiety Disorder, in particular, is characterized by a positive response to monoamine oxidase inhibitors (MAOIs) and selective serotonin reuptake inhibitors (SSRIs), but not to TCAs (Blanco et al., 2003; R. G. Klein & Pine, 2002; Liebowitz et al., 1988). Similarly, OCD is characterized by a pattern of response to serotonergic agents such as SSRIs and clomipramine, but not to nonserotonergic TCAs or MAOIs

(R. G. Klein & Pine, 2002; Pine, 2002b; Riddle et al., 2001). Other anxiety states, such as Panic Disorder and GAD, tend to respond to all three classes of medication (R. G. Klein & Pine, 2002). These relatively robust and consistent pharmacological findings in adults have led to parallel genetics and pathophysiology research on the differences, as well as the commonalities, among the anxiety disorders. Only recently have clinical trials begun to examine specificity of pharmacological effects in children (RUPP, 2001). To date, findings do not parallel those from adult studies, in that specific response patterns have not clearly been delineated for specific subtypes of childhood anxiety disorders.

Whereas adult psychopharmacological studies have yielded substantive evidence regarding specificity of anxiety states, developmental research from an epidemiological perspective has shed light on patterns of heterogeneity in outcome among anxiety states. Since LaPouse and Monk's (1964) classic study of behavior problems in children, a series of community-based epidemiological studies has documented alarmingly high rates of anxiety symptoms among children and adolescents (e.g., P. Cohen et al., 1993; Costello et al., 2003; Pine et al., 1998). Through the first half of the twentieth century, these symptoms were considered normal manifestations of behavior that waxed and waned across development. However, refinements in the standardized assessment of childhood psychopathology facilitated relatively large longitudinal studies that followed youth into adulthood. Such longitudinal studies found that even mild anxiety symptoms in young children and adolescents robustly predicted the onset of later, relatively serious clinical disorders, including MDD, Social Anxiety Disorder, OCD, and Panic Disorder (Costello et al., 2002; Peterson et al., 2001; Pine, Cohen, et al., 2001; Pine et al., 1998). However, although most adults with mood and anxiety disorders had experienced childhood anxiety, the majority of anxious children did not go on to develop adult disorders (Costello et al., 2002; Pine et al., 1998). This observation led to an increasing research emphasis on identifying factors that distinguished between mildly anxious children who would go on to develop serious mental disorders as adults and those who would experience only transient problems.

SOCIAL ANXIETY

In the following sections we provide an overview of social anxiety, both its normal and pathological manifestations, across development. In our examination of normative social

anxiety, we focus on its evolution during several developmental stages, as well as on adaptive approaches to managing social fears and concerns. We then shift our focus to more impairing levels of social anxiety and describe both the phenomenology of Social Anxiety Disorder and potential mechanisms underlying its development.

Normal Social Anxiety across Development

With the emerging emphasis on specificity in anxiety states, a focus on developmental changes in individual symptoms and symptom patterns has followed. This has stimulated a series of studies specifically on changes in social anxiety across development. By adulthood, a large proportion of people acknowledge having experienced at least transient social anxiety on occasion, predominantly regarding public speaking or performing in front of others (B. J. Cox, McWilliams, Clara, & Stein, 2003; Kessler, Stein, & Berglund, 1998). In a large telephone survey, 61% of randomly selected adult participants reported experiencing high levels of anxiety in at least one type of social situation (Stein, Walker, & Forde, 1994). The most commonly feared situation was public speaking, which 55% of the respondents endorsed as anxiety provoking. This type of fear appears to emerge early; 50% of surveyed individuals who endorsed anxiety about public speaking dated its onset to early adolescence, and 90% reported that it had emerged before they reached adulthood (Stein, Walker, & Forde, 1996). A variety of other social situations also frequently elicit anxiety. Speaking to small groups of familiar people was anxiety provoking for a quarter of the participants in Stein and colleagues' (1994) study, and large numbers of participants endorsed anxiety when dealing with people in authority (23.3%), attending social gatherings (14.5%), and interacting with new people (13.7%).

A relatively small number of adults experience social fears that are severe or chronic enough to meet criteria for Social Phobia. Among adult participants in the National Comorbidity Survey, 38.6% endorsed marked social fears of any type, but only approximately 33% of this group met criteria for lifetime history of Social Phobia (Kessler et al., 1998). Similarly, in a study comparing shy and nonshy college students, the disorder was significantly more common among shy individuals (18% affected) than among those who were not shy (3% affected) but was relatively uncommon in either group (Heiser, Turner, & Beidel, 2003).

Among youth, patterns of normal-range anxiety evolve across development. In general, anxiety and fearfulness are common among children. Among 4- to 12-year-olds, 67% report currently experiencing worries, and 75.8% report

current fears (Muris, Merckelbach, Gadet, & Moulart, 2000). Over time, these symptoms appeared to decline markedly, and other research has indicated that decreases in normal anxiety and fear continue into adolescence (Gullone, King, & Ollendick, 2001; Ollendick, King, & Frary, 1989). Anxiety specifically about social situations, however, shows a different pattern of development. As the following sections outline, interpersonally oriented anxiety shifts in focus from concerns about separation to concerns about evaluation as children pass from infancy through childhood and into adolescence.

Infancy and Early Childhood

Among infants and very young children, social anxiety, particularly fear of negative evaluation, is rarely reported or observed. Instead, during this developmental period, anxiety about separation is the predominant type of interpersonal concern. Studies examining the trajectory of separation anxiety among children demonstrate that it emerges around 6 to 8 months of age, peaks at around 15 months, and decreases over time (e.g., Kagan, Kearsley, & Zelazo, 1978). F. N. Cox and Campbell (1968), for instance, placed children between 13 and 47 months in a playroom for 12 minutes, during 4 of which their mother was absent from the room. The 13- to 15-month-old children showed significantly greater decreases in play, speech, and movement after their mother left the room than did older children, which suggested that the effects of separation were greatest in the youngest children. In a replication and extension of this study, Gershaw and Schwarz (1971) found not only that 15- to 29-month-old boys showed decreased play behavior relative to 31- to 42-month-old boys during maternal separation, but also that they cried and watched the door more while their mother was absent. Concerns about separation appear to persist into middle childhood, but with progressively decreasing frequency and intensity. For example, whereas 4- to 6-year-olds in one study reported separation from their parents as the topic that caused them the most worry, older children were much less likely to identify separation as a prominent source of concern (Muris et al., 2000). In fact, developmental stage represents one of the main factors that distinguish “normal” separation anxiety from pathological separation anxiety, or Separation Anxiety Disorder. This condition is typically characterized as an extreme form of normal separation anxiety that persists into the latency or early adolescent years, when normal separation anxiety is expected to wane.

It is not entirely clear when other types of socially oriented fear and anxiety, including fear of negative evalua-

tion, initially emerge. Studies of normal variations in temperament indicate that some children may be vulnerable to these and other fears from a very early age. In a classic series of studies, Kagan and colleagues found marked individual differences in patterns of response to both social and nonsocial novelty in a large sample of children followed longitudinally from early infancy to adulthood (Kagan, 1997). At 4 months of age, approximately 20% of the sample showed marked signs of distress when presented with novel stimuli; of these children, approximately a fifth went on to show both consistently high levels of fear as toddlers and a timid pattern of interaction as preschoolers. Among these children, whom Kagan termed “behaviorally inhibited,” rates of Social Phobia at age 11 years were elevated relative to rates among uninhibited peers (Kagan, Reznick, & Snidman, 1988). This basic pattern of findings has been replicated in other laboratories (Fox, Henderson, Rubin, Calkins, & Schmidt, 2001). Clearly, at least some inhibited children show a heightened vulnerability to social fears; however, it remains unclear whether such concerns emerge earlier in these children than in other subsets of youth.

Studies on the development of embarrassment among toddlers and preschoolers in general suggest that social fears are preceded developmentally by a sort of bashfulness in the face of scrutiny or attention and by the emergence of shame. In an observational study of preschoolers, Lewis and colleagues (Lewis, Stanger, Sullivan, & Barone, 1991) described the behavior of 22-month-old and 35-month-old children in a variety of situations designed to elicit embarrassment. Of the 22-month-olds, 52% showed behavioral signs of embarrassment, such as smiling while averting their gaze and touching their face or body when they were pointed to, asked unexpectedly to dance, or complimented. Such behaviors were even more common among the 35-month-old children, 83% of whom acted in an embarrassed manner.

Because this type of embarrassment reflects “exposure of the self when the individual is the object of attention from others” rather than negative evaluation in performance situations, Lewis and Ramsay (2002, p. 1034) refer to it as “exposure embarrassment.” “Evaluation embarrassment,” which is evident in the context of perceived failure or negative feedback, appears to emerge later in development, around the age of 3 years (Lewis, Alessandri, & Sullivan, 1992), and to be associated with elevated cortisol (Lewis & Ramsay, 2002). This developmental progression is thought to reflect changes during early childhood in self-awareness and in capacity to evaluate one’s performance against external standards (e.g., Lewis & Ramsay, 2002;

Stipek, Gralinski, & Kopp, 1990). Further, although very young children appear capable of experiencing both types of embarrassment, some evidence suggests that explicit awareness of the two distinct constructs emerges even later in development (Crozier & Burnham, 1990).

In studies that have presented young children with hypothetical scenarios about potentially embarrassing situations, other developmental trends have been evident. For example, when 5-year-old and 8-year-old children were read vignettes in which a person's actions were greeted with either a supportive or a derisive response and then asked how they would feel if they had been the person in the vignette, their responses varied with age (Bennett, 1989; Bennett & Gillingham, 1991). Whereas all children reported that they would have felt embarrassed in the face of derision, only the older children said that they would have been embarrassed when others expressed support. The authors postulate that this difference in pattern of response reflects cognitive differences between the preschoolers and the older children, such that the younger children were less aware that some situations could be intrinsically embarrassing, regardless of others' reactions. Findings from another study suggest that 5-year-old children are also less likely than 8- or 11-year-old children to feel embarrassment when someone else, with whom they are associated, publicly violates a rule (Bennett, Yuill, Banerjee, & Thomson, 1998).

It appears clear that very young children experience emotional responses to situations that involve potential negative evaluation, even though their responses differ in several ways from those of older children. Little research, however, has examined preschoolers' capacity and proclivity to anticipate or worry about negative feedback from others. Results from the few studies of normative worry among preschoolers suggest that such concerns may be present at a fairly young age, even if children do not articulate them. When 5- to 6-year-old children were interviewed directly, they reported few evaluative worries relative to older children (Vasey, Crnic, & Carter, 1994). When preschoolers' parents were asked about their children's worries, however, they reported that their 3- to 5-year-old children frequently worried about meeting new people or entering groups of children (Spence, Rapee, McDonald, & Ingram, 2001). Parents of 4- and 5-year-old participants also reported that their children commonly feared talking in front of a group, and 5-year-olds, according to their parents, worried about appearing stupid in front of others.

Regardless of the source of their social inhibition, however, a subset of preschoolers are readily identifiable by observers as excessively shy. A study of 4-year-olds found

that these highly shy children, relative to peers who show average or low levels of shyness, are prone to experience negative moods, pervasive worries and fears, and poor adjustment (Stevenson-Hinde & Glover, 1996). Further, both tendencies toward shy behavior and their associated problems appear to persist in these children. When Stevenson-Hinde and colleagues (Fordham & Stevenson-Hinde, 1999) reexamined their longitudinally followed sample at the ages of roughly 8 to 10 years, they found shy behavior to be highly consistent over time. Additionally, shy behavior and social adjustment difficulties, including perceived poorer friendship quality, trait anxiety, and lower ratings of global self-worth, were significantly related, particularly in the older children in the sample.

Middle Childhood and Adolescence

During later childhood and adolescence, socially oriented concerns increase (Westenberg, Drewes, Goedhart, Siebelink, & Treffers, 2004). In their interview study of children's fears between 4 and 12 years, Muris and colleagues (2000) found that whereas fears regarding some topics, including animals and safety, were prevalent across the entire age span, worries about evaluation were more evident in older children. Similarly, in a study of normal children's worries between second and sixth grades, concerns about performance in school (e.g., getting good grades, being called on in class) were among the most common, along with worries about health and personal safety (Silverman, La Greca, & Wasserstein, 1995). Of the more common worries reported across 14 categories, 22% pertained to interpersonally relevant issues such as peer rejection, neglect, or scapegoating; personal appearance; or concern about others' feelings. When performance-related concerns, which often also involve social-evaluative components, were included, 40% of the worries could be classified as interpersonally related.

Among healthy adolescents, social-evaluative concerns are widely prevalent; some evidence suggests that this is particularly true for girls. West and Sweeting (2003) interviewed two cohorts of 15-year-olds about their worries and found that for girls, the most consistently prevalent worries were about school performance (40.1% and 45.6%) and weight (29% and 38.3%), whereas for boys, the most prevalent concerns were school performance (39.1% and 35.6%) and unemployment (35.6% and 25%). Anxiety about dating also appears to be common among adolescents, particularly those in their middle teens, and to be distinguishable from more global social anxiety (Glickman & La Greca, 2004).

Similar patterns of worry were evident in a sample of 6- to 16-year-old youth diagnosed with anxiety disorders

(Weems, Silverman, & La Greca, 2000). Like the children in Silverman and colleagues' (1995) community sample, these children and adolescents were most likely to worry about safety and school performance. These children differed from participants in Silverman and coworkers' study primarily in the intensity of their worries rather than the content or frequency of worry. Interestingly, the clinical sample in this study reported fewer worries on average than did high anxious children in the community sample.

Most studies of worries among children and adolescents have used self-report measures or interviews to gather data. Although these approaches have clear advantages, particularly in light of evidence that parents and teachers tend to underestimate internalizing symptoms among youth (R. G. Klein & Pine, 2002), they also have some limitations. As Gullone (1999) has pointed out, the marked variability among youth of different ages, their reporting biases, their awareness of their own internal states, and their verbal and cognitive skills must be taken into account when interpreting findings based on child and adolescent self-report.

Social Anxiety and Coping Skills

Although social-evaluative concerns are common among school-age children and adolescents, youth vary in the degree to which they cope successfully with these concerns. A large body of literature indicates that instrumental, problem-focused coping techniques that involve voluntary shifts of attention away from negative feelings are particularly effective for managing worry and emotional discomfort (Clark, Beck, & Stewart, 1990; R. G. Klein & Pine, 2002; MacLeod, Rutherford, Campbell, Ebsworthy, & Holker, 2002). Individuals with high levels of social fears or shyness are less likely than peers to use such coping methods (Glyshaw, Cohen, & Towbes, 1989; Mellings & Alden, 2000), instead relying on avoidance, rumination, and other strategies that do little to alleviate their discomfort (Garnefski, Legerstee, Kraaij, Van Den Kommer, & Teerds, 2002; Hymel, Woody, & Bowker, 1993).

The ability to shift attention away from negative internal states may be especially critical to the management and prevention of social anxiety. Ruminative or emotion-focused coping strategies, for example, which involve sustained focus on internal discomfort, have been shown to relate to elevated levels of anxiety (Blankstein, Flett, & Watson, 1992; Rose, 2002). The direction of the association with coping style is unclear, but some evidence suggests that skill at such voluntary redirection of attention from threat cues to neutral cues may modulate the effects of anxiety on coping (Derryberry & Reed, 2002). Addi-

tionally, the tendency to internalize and focus attention on negative emotions during preschool has been shown to predict shy behavior 4 to 6 years later (Eisenberg, Shepard, Fabes, Murphy, & Guthrie, 1998). These findings suggest that poor attentional control during negative emotional states may amplify later anxiety and anxious behavior. We discuss the role of such cognitive skills in the development and maintenance of social anxiety in more detail in the section on anxiety and neuroscience.

Clinical-Range Social Anxiety: Social Phobia

Although the experience of transient social anxiety is normative, symptoms are persistent and impairing for a subset of the population. In the following section we describe clinically significant manifestations of social anxiety and factors that may contribute to their emergence.

Clinical Presentation

As noted earlier, the diagnosis of Social Anxiety Disorder or Social Phobia is based on the presence of fear or anxiety about situations in which an individual may be scrutinized. These situations may be social, as in parties or school gatherings, or they may be academic or work related. In both the generalized form of Social Anxiety Disorder, where most social situations are feared, and in the specific form, which consists of an isolated fear of public speaking, anxiety must be of sufficient severity to cause extreme distress or impairment. The broad definition of Social Anxiety Disorder has changed relatively little since the publication of *DSM-III* in 1980, but there has been increasing recognition in recent years of the need to integrate data on distress and impairment into assessments of social anxiety symptoms. Such a shift of emphasis to impairment is likely to influence the threshold differentiating clinical and subclinical manifestations of social anxiety.

Rates of Social Phobia appear to increase as children, particularly girls, pass through adolescence and into adulthood (Costello et al., 2003; McGee, Feehan, Williams, & Anderson, 1992; Pine et al., 1998; Wittchen, Stein, & Kessler, 1999). In the Great Smoky Mountain Study sample, 3-month prevalence rates rose from 0.3% in 9- to 11-year-old children to 1.1% when these youth reached 15 years of age (Costello et al., 2003). This change was largely driven by increased prevalence of the disorder among girls. Pine and colleagues (1998) also found marked gender difference in the prevalence of Social Phobia across development. For girls in this study, 12-month prevalence rates remained relatively stable, ranging from 10.1% when the sample was 9 to 18 years old to 12.5% 2 years subsequently

and 9.5% after an additional 7 years. For boys, in contrast, rates declined over time from 6.7% and 6.8% at the first two time points to 1.7% at the most recent one. The nearly 10-fold difference in rates of Social Anxiety Disorder between these two longitudinal epidemiological studies is highly notable. This variation may reflect differences in sampling procedures or demographics across the two samples. However, differences in assessment and categorization are also likely to contribute heavily to the disparate findings across studies. To meet criteria for a diagnosis in Costello and colleagues' study, participants were required to demonstrate more evidence of clinically significant distress or impairment than were participants in Pine and coworkers' research.

Consistent across both studies, however, are findings that rates of Social Anxiety Disorder increase across development in females, but not in males (see Figure 12.1). Further, developmental gender differences in prevalence are comparable for normal social fears and frank Social Anxiety Disorder. Both phenomena appear to peak in adolescence, particularly among girls. From adolescence onward, gender differences in prevalence remain largely constant.

Although anxiety disorders and symptoms often have been considered transient or minimally impairing conditions, longitudinal research in children and adolescents suggests otherwise. In a large study of 9- to 16-year-olds, presence of an anxiety disorder was associated with a

Figure 12.1 Gender differences in rates of social phobia in a longitudinally studied sample at three time points. Graph based on data from “The Risk for Early-Adulthood Anxiety and Depressive Disorders in Adolescents with Anxiety and Depressive Disorders” by D. S. Pine, P. Cohen, D. Gurley, J. S. Brook, and Y. Ma, 1998, *Archives of General Psychiatry*, 55(1), pp. 56–64.

nearly threefold increase in risk for future dysfunction, particularly in terms of family relationships. These rates were comparable to those for other disorders, particularly depression, which is often considered more impairing than anxiety (Ezpeleta, Keeler, Erkanli, Costello, & Angold, 2001). Elevated risk for other problems, such as school dropout, is also associated with the presence of an anxiety disorder during adolescence (Vander Stoep, Weiss, McKnight, Beresford, & Cohen, 2002). Among anxious youth, other types of psychopathology are common, both concurrently and later in development. In a community sample of adolescents who kept electronic diaries over a 4-day period, for example, those who reported moderate to high levels of anxiety symptoms also more frequently reported feeling sad, angry, stressed, and hassled than did low-anxiety peers (Henker, Whalen, Jamner, & Delfino, 2002).

Relatively few studies have examined outcomes of childhood anxiety disorders, let alone outcomes that are specific to a particular diagnosis, such as Social Anxiety Disorder. Of the existing findings regarding outcome, some of the most reliable come from prospective community-based studies, which are free of the referral and recall biases that limit conclusions from studies using other designs. Using a community-based sample, Pine and colleagues (1998) prospectively examined relationships between adolescent and adult anxiety disorders and noted a relatively specific association between Social Anxiety Disorder diagnoses in adolescence and in adulthood. Adult Social Anxiety Disorder, however, also related to other childhood anxiety disorders, including childhood Over-anxious Disorder/Generalized Anxiety Disorder. Similarly, Pine Cohen, Cohen, and Brook (2000) noted a highly specific relationship between Social Anxiety Disorder and Conduct Disorder. Unlike other anxiety disorders, Social Anxiety Disorder predicted a relatively benign course for subsequent Conduct Disorder. Such longitudinal associations are consistent with data on psychopathy, which is characterized both by low levels of anxiety and by chronic, recurrent behavior problems (Blair, 2003). Research on adult psychopathy and Social Anxiety Disorder, as reviewed later in the chapter, implicates dysfunction in a common underlying neural circuit that encompasses the amygdala and ventral prefrontal cortex.

Relatively little community-based longitudinal research has examined outcome in children or adolescents with specific anxiety disorders; a notable exception is Pine et al.'s (1998) study. The few such available studies that have specifically focused on Social Anxiety Disorder have found that it predicts a broader array of conditions than did Pine and colleagues. For example, Stein and coworkers

(2001) found that Social Anxiety Disorder related to both mood and anxiety disorders in a sample of adolescents and adults followed longitudinally. However, associations with mood disorder were stronger in the older participants in this study than in the younger participants. Further, with respect to clinical samples, Last, Hansen, and Franco (1997) reported generally positive outcomes for Social Anxiety Disorder and for other pediatric anxiety disorders. More recently, follow-up research on youth treated with cognitive-behavioral therapy for anxiety disorders suggests that treatment enhances the likelihood of enduring positive sequelae (Kendall, Safford, Flannery-Schroeder, & Webb, 2004).

Few family genetic studies have explicitly examined associations between Social Anxiety Disorder in parents and their children. However, a relatively large series of studies document comparable relationships among family members. For example, Social Anxiety Disorder in an adult proband confers a strong and specific risk for the disorder in first-degree relatives when comorbidity is properly controlled (Fyer, Mannuzza, Chapman, Liebowitz, & Klein, 1993; Fyer et al., 1995). Studies focused on children also note associations between parent and offspring anxiety disorders (e.g., Mancini, van Ameringen, Szatmari, Fugere, & Boyle, 1996; Unnewehr, Schneider, Florin, & Margraf, 1998). Further, one study explicitly linked Social Anxiety Disorder in a parent to shyness in the children (Cooper & Eke, 1999). No specific associations between parent and child Social Anxiety Disorder per se, however, have been demonstrated.

Pathways to Social Phobia: Risk and Protective Factors

The developmental psychopathology perspective emphasizes that multiple pathways can lead to the onset of psychopathology and that a wide variety of factors can confer risk or protection. With regard to Social Anxiety Disorder, previous reviews have outlined numerous factors hypothesized to contribute to risk (Hudson & Rapee, 2000; Ollendick & Hirshfeld-Becker, 2002; Vasey & Dadds, 2001). We examine several of these, including genetics, temperament, parenting, conditioning events, and, in the final section of the chapter, neurocognitive factors.

Genetic Factors

As the family studies described earlier suggest, Social Anxiety Disorder appears to aggregate within families. Using

twin designs, several behavioral genetic studies have examined the relative contributions of hereditary and environmental factors to this tendency for the disorder to be familial. For example, results from studies examining a large population-based sample of adult female twins indicate a significant, albeit modest, genetic component, with heritability estimates of 30% to 50% (Kendler, Karkowski, & Prescott, 1999; Kendler, Neale, Kessler, Heath, & Eaves, 1992). Findings from a subsequent study of adult male twins from the same sample yielded a comparable heritability estimate of 31% for the disorder and associated irrational social fears. Of note, similar, relatively modest degrees of heritability are found for most anxiety disorders, including Panic Disorder and Generalized Anxiety Disorder.

Although these studies suggest that genetic factors play similar roles in the onset of social anxiety for males and females, gender differences in the prevalence of the disorder, particularly during adolescence, have led to questions about the impact of gender on risk. The one twin study to date that has directly compared genetic and environmental risk across males and females found evidence consistent with gender differences in patterns of liability (Kendler, Jacobson, Myers, & Prescott, 2002). According to this study, whereas twin resemblances among females were predominantly due to family environment, resemblances in males largely reflected genetic factors. The authors caution, however, that the strong effect of family environment seen in females is inconsistent with their previous findings and note that such effects have occurred by chance in studies of other disorders.

In recent years, researchers have begun to conduct molecular studies aimed at identifying candidate genes for Social Anxiety Disorder and related constructs such as shyness. In light of pharmacological and biological evidence that the serotonin and dopaminergic systems may be dysregulated in Social Anxiety Disorder (Blanco et al., 2003; Pine, 2001; Schneier et al., 2000), some research has focused on potential candidate genes within these systems. In a study of clinic-referred children, symptoms of Social Anxiety Disorder, along with symptoms of other anxiety disorders and Tourette's syndrome, were found to relate significantly to the number of 10-repeat alleles of the dopamine transporter gene (DAT1; Rowe et al., 1998). In contrast, Stein, Chartier, Kozak, King, and Kennedy (1998) found no evidence of linkage for either the serotonin transporter gene (SLC6A4) or the serotonin type 2A receptor gene (5HT_{2A}R) in a sample of 17 probands with generalized Social Anxiety Disorder and their family members. However, as the authors note, linkage analysis may not be

an optimal approach for studying complex psychiatric disorders. Instead, genomic association studies, which can detect relatively weak effects, may be necessary to shed light on the genetic basis of Social Anxiety Disorder (Stein et al., 1998).

Studies focused on broader behavioral styles that may relate to Social Anxiety Disorder, such as behavioral inhibition (BI) and shyness, have yielded modest associations with potentially relevant genetic polymorphisms. Results from a family-based association study of BI indicated a small but significant association between BI and the glutamic acid decarboxylase gene (65 kDa isoform; Smoller et al., 2001). This gene, which is involved in the synthesis of the neurotransmitter GABA, was targeted because it had previously been implicated in mouse models of BI. Additionally, in a sample of second graders, Arbelle and colleagues (2003) found a small but statistically significant association between shyness and the long form of the serotonin transporter promoter region 44 base pair deletion/insertion polymorphism (5-HTTLPR; Arbelle et al., 2003).

It appears clear that genetic factors play a role in the development of Social Anxiety Disorder. Much remains to be learned, however, about the specific genes involved and the ways their expression varies as a function of environmental factors and developmental stage. Large-scale genetic association studies and translational approaches, such as knock-out studies that manipulate the expression of specific genes in rodents, are among the promising methods for addressing such questions.

Temperamental Factors

Certain temperamental variations may constitute risk factors for the later development of Social Anxiety Disorder. As we noted earlier, some evidence suggests that behavioral inhibition to the unfamiliar may relate to later social anxiety. In relatively small, intensively studied samples, several studies have shown associations between BI and Social Anxiety Disorder in both affected children and their family members, particularly if the BI remains stable throughout early childhood (Biederman, Hirshfeld-Becker et al., 2001; Hirshfeld et al., 1992; Rosenbaum et al., 1991; Schwartz, Snidman, & Kagan, 1999). Other research, however, has found such associations to be small when examined in a larger, less precisely selected sample of children studied with a less intensive temperament assessment battery (Prior, Smart, Sanson, & Oberklaid, 2000).

Some physiological evidence indicates parallels between children with BI and individuals with social-evaluative fears or Social Anxiety Disorder. Correlations between BI

and a variety of physiological variables, including heart rate, morning salivary cortisol, and activation of neural structures thought to mediate withdrawal or avoidance resemble those found in youth and adults with social-evaluative fears or Social Anxiety Disorder (Beidel, 1988; Davidson, 1994; Heimberg, Hope, Dodge, & Becker, 1990; Kagan et al., 1988). Additionally, findings from one functional magnetic resonance imaging (fMRI) study suggest that high BI in infancy modestly predicts adult amygdala response to novel social cues (Schwartz, Wright, Shin, Kagan, & Rauch, 2003). Such a response is consistent with findings among adults with Social Anxiety Disorder of amplified amygdala activity in the presence of novel facial cues, particularly those that signal potential threats (Birbaumer et al., 1998; Stein, Goldin, Sareen, Zorrilla, & Brown, 2002).

Some controversy remains regarding associations between BI and anxiety disorders. In a critical review of the literature, Turner, Beidel, and Wolff (1996) pointed out two central limitations. First, studies vary widely in the stringency with which they identify BI. Whereas some BI samples were selected on the basis of consistently inhibited behaviors across multiple tasks, others were identified on the basis of parent report alone. These differences in the ways that participants were classified make it difficult to compare results across studies. Second, studies do not always provide data regarding the psychiatric histories of participants' parents. In the absence of such data, it is not possible to differentiate the effects of BI and the effects of a family history of anxiety disorders.

Other researchers have raised questions about the degree to which BI relates to the emergence of social-evaluative concerns. Asendorpf (1990, 1993) argued that temperamental inhibition is associated with wariness of unfamiliar people, but not with social-evaluative concerns and associated patterns of behavior. Instead, he contended that the quality of children's relationships with peers predicts the degree to which they exhibit social inhibition and evaluative fears, particularly in familiar settings such as the classroom. Although there is some evidence in support of this distinction in healthy children (Eisenberg et al., 1998), its relevance to youth with Social Anxiety Disorder remains unclear.

Parental Influences

Parenting behavior has long been considered a potential mechanism underlying the development of anxiety in children. According to a model that Craske (1999) has proposed, parenting can contribute to anxiety in several ways.

First, certain broad, pervasive styles of parenting may facilitate the development of general anxiety in children. Parents whose styles tend to be critical or controlling, for example, might create a home environment that is conducive to anxiety in their offspring. Second, specific parenting behaviors, such as expression of apprehension when the child engages in a potentially risky activity, may encourage the development of anxiety in specific contexts or around specific topics. Most research on anxiety and parenting behavior has targeted general rather than specific forms of anxiety; very few studies have concentrated on how parenting may figure in the development of social anxiety *per se*.

A considerable body of research has examined associations between general parenting styles and the development of child anxiety, with a particular focus on control, warmth, and acceptance. In a recent critical review of this literature, little evidence emerged that these broad parental styles relate meaningfully to child anxiety (Wood, McLeod, Sigman, Hwang, & Chu, 2003). The authors note, however, that most studies were limited by their use of nonrepresentative samples and global self-report measures of parenting style. Additionally, as Rapee (1997) pointed out, a number of studies relied on participants' recollections of their parents' child-rearing practices, yielding data that may have been affected by reporting or recall biases.

A much smaller body of work has focused on observed parenting behaviors in the context of specific family interactions. In their review of these studies, Wood and colleagues (2003) found some support for a concurrent association between maternal criticism and child anxiety. A similar relationship between maternal acceptance and child anxiety also emerged in some cross-sectional studies; however, consistent with McClure, Brennan, Hammen, and Le Brocque's (2001) findings regarding general parenting styles in a longitudinally followed sample, this relationship may have been driven by maternal anxiety. Whether specific parenting behaviors mediate the relationship between parent and child anxiety is unclear; findings from one recent observational study, however, suggest that any such mediation may be minimal (Turner, Beidel, Roberson-Nay, & Tervo, 2003). In this study, which compared anxiety disordered and nonanxious parents' behaviors as they observed their children engaging in mildly risky play activities, few between-group differences emerged.

Conditioning Events

Theorists from behavioral perspectives have hypothesized that learning experiences may play a role in the onset of youth fears and anxieties. Rachman (1977) proposed that

three types of learning or conditioning events contribute to the development of anxiety. The first type, direct conditioning, involves *in vivo* exposure to an aversive stimulus (e.g., the child is mocked while presenting a book report to classmates). The second type, vicarious conditioning, involves observation of another individual's fearful behavior around an aversive stimulus (e.g., the child observes an older sibling's fear before presenting a book report). The final type, instruction/information, involves hearing from others that stimuli are fear inducing (e.g., the child hears stories from peers about bad experiences during the presentation of book reports).

In general, findings are mixed regarding these three pathways to the onset of fears and anxieties. King, Gullone, and Ollendick (1998) summarized research findings from studies that examined the role of learning in the acquisition of a variety of specific phobias and found that results varied markedly. Whereas most participants in some studies cited conditioning events as precipitants of a phobia, most participants in others reported having "always been afraid" of the phobic stimulus. Most of the studies reviewed were limited by their use of retrospective parent or child reports and the absence of meaningful comparison participants; consequently, it is difficult to draw conclusions from this literature.

More recent studies have used prospective designs to measure the effects of different types of conditioning on the development of fears or anxieties. In one of the few studies to focus on the role of learning in the development of social fears, Field, Hamilton, Knowles, and Plews (2003) measured 10- to 13-year-old children's attitudes toward three types of potentially frightening social situations (public speaking, eating in public, meeting new children) both before and after the presentation of either positive, neutral, or negative information about each situation. Results provided some support for Rachman's (1977) theory, but demonstrated that the effects of information on fear varied according to whether a peer or a teacher provided the information. Further work using prospective designs and *in vivo* encounters with conditioned stimuli is needed before the roles of different learning types in the onset of anxiety are fully understood.

Summary Regarding Risk

Consistent with the developmental psychopathology assumption of multideterminism (Cicchetti & Cohen, 1995), a wide range of factors clearly interact to influence the onset of anxiety in general and social anxiety in particular. Biologically based factors, such as genetic predisposition and temperament, appear particularly important for fur-

ther study, especially in light of the neuroscience findings presented in the last section of this chapter. Nonetheless, given that social anxiety, like other types of anxiety, is likely multiply determined, it will be important for future research to examine the many potential risk factors, both those that are primarily biological and those that are primarily environmental, in concert. Consideration of the context in which anxiety symptoms and disorders develop will also be critical in light of evidence that different types of life events and experiences relate differently to the onset of different types of psychopathology (Tiet et al., 2001).

ANXIETY FROM A NEUROSCIENCE PERSPECTIVE

Research reviewed in the preceding sections of this chapter on clinical, developmental, and familial aspects of anxiety raises three essential questions for which current data provide few answers. First, it is not clear where the boundary lies between developmentally appropriate adolescent increases in social anxiety and clinical manifestations of an anxiety disorder, such as Social Anxiety Disorder. Both typical and pathological social anxiety become increasingly common as youth enter adolescence, and it is difficult to distinguish cases that are normal from those that are potentially problematic. Second, it remains unclear how to identify those youth affected by an anxiety disorder who will go on to develop chronic problems with anxiety and mood disorders. Although anxiety disorders represent the most common class of psychiatric disorder in children, with Social Anxiety Disorder particularly prevalent during adolescence, only a minority of affected youth will suffer significant long-term clinical effects. It is important that this minority be identified prospectively because, as its members mature, they will go on to account for a large proportion of adults with mood and anxiety disorders. Third, it remains unclear how to differentiate at-risk adolescents who are particularly vulnerable to developing anxiety disorders from those who are likely to be resilient. Despite the strong associations between various risk factors, particularly parental psychopathology, and childhood anxiety disorders, a sizable proportion of youth exposed to such risk factors will not develop clinical disorders.

There is no shortage of clinical research that has attempted to answer these three basic questions. Nevertheless, answers have not readily been forthcoming (Pine, 2002a, 2003; Pine & Charney, 2002). One alternative means of pursuing answers to these clinical questions involves embracing recent insights from neuroscience re-

search. Ultimately, variations in many domains of human experience, including anxiety, are reflected in functional aspects of neurophysiology. As a result, knowledge about how neurophysiology relates to anxiety may provide clinicians with novel tools for identifying children who are particularly at risk or resilient. Such advances in knowledge are unlikely to occur soon because it is difficult to translate research on neurophysiology into clinical insights. Basic and clinical studies have traditionally targeted different levels of inquiry, with basic science focusing on general aspects of behavior and its development, and clinical research focusing on between-group differences in behavioral patterns and developmental trajectories. Research on anxiety provides an excellent starting point for integrating basic and clinical studies. Already, considerable neuroscience research has examined the role of neural circuits in anxiety-related behaviors. In the current section, we review insights from this research that may ultimately provide a basis for breakthroughs in clinical investigations.

Fear Conditioning

In the late 1970s, research in the neurosciences shifted away from a relatively restricted focus on basic aspects of perception and motor control. Following the work of Davis (Davis & Whalen, 2001), LeDoux (2000), and others, investigators began to trace neural circuits that were engaged when animals experienced emotions or changes in brain states associated with reward and punishment. Much of this work initially concentrated on fear, as punishing stimuli produce robust changes in behavior, information processing, and physiology that are markedly similar across a range of mammalian species. In particular, neuroscientists developed a keen interest in the process of fear conditioning.

In the standard fear conditioning experiment, as shown in Figure 12.2, a neutral conditioned stimulus (CS+), such as a tone or a light, is paired with an aversive unconditioned stimulus (UCS), such as a shock or an aversive air puff. Following a series of such pairings, presentation of the CS+ begins to elicit behaviors, information-processing patterns, and physiological responses that were formerly associated with presentation of the UCS. Over the past 30 years, the neural circuitry engaged by this process has been precisely delineated in rodents, nonhuman primates, and, more recently, humans. Current understanding of this “fear circuit” extends to the genetic level, with recent findings identifying specific genes that are activated in isolated sets of neurons (Fanselow & LeDoux, 1999; Killcross, Robbins, & Everitt, 1997; LeDoux, 2000). Information concerning

Training

Figure 12.2 Fear conditioning experiment. After the animal is familiarized with the experiment context, a tone, which serves as the neutral conditioned stimulus (CS+), is paired with a foot shock, which acts as an aversive unconditioned stimulus (UCS). Following a series of such pairings, presentation of the CS+ alone elicits a fear response that was formerly associated with presentation of the UCS. *Source:* From *Memory: From Mind to Molecules* by Larry R. Squire and Eric R. Kandel. Copyright © 1999 by Scientific American Library. Reprinted by permission of Henry Holt and Company, LLC.

perceptual aspects of the CS+ is processed in two neural pathways. One of these extends from peripheral perceptual organs (e.g., the ears or eyes) to the thalamus, a relay station for information processed in sensory modalities. From the thalamus, projections arise that directly innervate the amygdala, a collection of nuclei located in the anterior medial temporal lobe of mammals. The other pathway extends from the thalamus to posterior portions of the cerebral cortex that are devoted to processing perceptual aspects of stimuli encountered in the environment. These cortical neurons form a complex web of interconnected synapses that ultimately innervate the amygdala after information passes to relatively anterior portions of the posterior hemisphere (LeDoux, 2000).

Fear conditioning research has led to a detailed understanding of functional aspects of the amygdala in rodents and nonhuman primates (Davidson et al., 2002; Davis & Whalen, 2001; LeDoux, 1998, 2000). Conditioning or emotional learning occurs as a consequence of changes in gene expression in amygdala neurons. These gene-level changes

in turn lead to conditioning-linked alterations in behavior, information processing, and physiology (Meaney, 2001a). The precise roles that specific amygdala nuclei play in fear conditioning are the topic of some controversy. In one account (LeDoux, 2000), perceptual information is channeled through the basolateral nucleus, where long-term potentiation facilitates new learning. Information then progresses through the central nucleus, which has widespread connections with brain structures involved in behavioral, cognitive, and physiologic regulation. As it disseminates via these connections, broad changes in physiology, information processing, and behavior occur. In other accounts (Everitt et al., 1999; Everitt & Robbins, 2000; Killcross et al., 1997; Robbins & Everitt, 2002), pathways restricted to the basolateral nucleus mediate some forms of conditioning. Despite this uncertainty about which amygdala nuclei participate in specific types of emotional learning, there is broad agreement that cortical-amygdala circuitry plays a critical role in the processes, particularly in the context of fear conditioning. Although the same circuitry figures in other types of emotional learning besides fear conditioning, detailed discussion of these learning types is beyond the scope of the current chapter.

Insights into neural aspects of fear conditioning have generated great interest among clinically oriented investigators. Using neuroimaging and brain lesion techniques, these investigators have demonstrated that the circuit operating during fear conditioning in human adults parallels that found in rodents and nonhuman primates (Buchel & Dolan, 2000). This circuit encompasses the human thalamus, posterior neocortex, and amygdala. More recently, studies using adaptations of the fear conditioning experiment that are appropriate for children and adolescents have extended knowledge about developmental aspects of emotional learning and its neural basis (Grillon, Dierker, & Merikangas, 1998; Merikangas, Avenevoli, Dierker, & Grillon, 1999; Monk, Grillon, et al., 2003; Pine, Fyer, et al., 2001).

It initially appeared that neuroscience research on fear conditioning would provide an avenue for extending insights from behavioral research on emotional learning in anxiety disorders. In particular, patients with anxiety disorders were hypothesized to exhibit enhanced fear conditioning relative to healthy individuals (Gorman, Kent, Sullivan, & Coplan, 2000). Such findings would have created an arena where clinical and neuroscience research converged naturally, permitting translational research focused explicitly on elucidating anxiety at a neural level. Demonstrating such between-group differences in fear conditioning, however, has proved difficult. Indeed, some

evidence has even emerged to suggest that anxiety disorders are associated with *deficits* in fear learning in the context of fear conditioning paradigms (Grillon, 2002).

Translational Research and Anxiety: Going beyond Fear Conditioning

The exchange between basic and clinical researchers regarding fear conditioning has provided an exciting model for further translational research endeavors. Based on this body of research, basic researchers have begun to examine processes beyond fear conditioning with the aim of understanding how these processes may inform clinical studies. Some of this research focuses on processes that conform to our narrow definition of emotion regulation. Research on extinction provides a particularly compelling example.

Following the instantiation of fear through conditioning, the response to a CS+ can be changed or eliminated through a process known as “extinction.” Extinction, which involves repeated presentation of the CS+ in the absence of the UCS, maps neatly onto our concept of emotion regulation. The animal’s initial response to the newly conditioned CS, for instance, parallels the “emotional reaction” in Thompson’s (1994) definition of emotional regulation. Then, during the process of extinction, the animal regulates its response in a manner resembling the monitoring, evaluating, and modifying that forms the substance of emotion regulation.

Conceptualizations of the extinction process have changed based on findings in neuroscience over the past decade. Formerly, models of extinction emphasized a process of “forgetting,” in which an organism no longer recalled the salience of the CS+, as a predictor of shock once the CS+ had been extinguished (Bouton, 2002). However, recent data suggest that extinction is a far more active process that occurs when new learning overlays the results of conditioning (Bouton, 2002; Bouton, Mineka, & Barlow, 2001). Some have suggested that extinction “contextualizes” knowledge of the CS+-UCS relationship (Bouton et al., 2001). In a sense, extinction involves learning that a CS+ predicts a UCS in some contexts but not in others.

At a neural level, this process engages a broader circuit than the one linked to fear conditioning. This circuit encompasses the amygdala, ventral and medial aspects of the prefrontal cortex (PFC), and the hippocampus (Bouton, 2002; Davis & Whalen, 2001; Grillon, 2002; LeDoux, 2000; Milad & Quirk, 2002; Quirk, 2002; Quirk & Gehlert, 2003) and likely includes structures that are critical to aspects of human fear-related behaviors and psychiatric symptoms (see Figure 12.3). Consistent with this possibility, clinical re-

Figure 12.3 Neural structures thought to participate in regulation of fear and other emotions. searchers have been more successful in demonstrating that extinction processes differ across healthy and anxious individuals than they have in demonstrating comparable between-group differences in fear acquisition (Grillon, 2002). Such clinical advances have even led to the piloting of novel potential anxiolytic pharmacological compounds, such as D-cycloserine, that are known to facilitate extinction in rodents (Grillon, 2002).

Contextual stimuli have been found to play a role in extinction in rodents (Bouton, 2002); consequently, research has begun to examine the relevance of context for fear learning across species. During the classic fear conditioning experiment, rodents not only develop a fear response to the CS+, but they also, through a process known as “conditioning to context,” develop a new reaction to the context in which the CS+-UCS relationship has been embedded (Davis, 1998). Thus, when placed in the cage used for the fear conditioning experiment, even in the absence of the CS+ or UCS, the rodent shows changes in behavior, physiology, and information processing (see Figure 12.2, testing in context). Like extinction, context conditioning is thought to involve neural circuits that extend beyond the amygdala,

encompassing regions implicated in emotion regulation (Davis, 1998).

Based on neurochemical data in rodents and psychophysiology data in humans with anxiety disorders, Davis (1998) has suggested that context conditioning, much like extinction, engages neural structures and information-processing functions more closely related to clinical anxiety disorders than do simple forms of cue-specific fear conditioning. Accordingly, he has embarked on a more general consideration of context and anxiety, with a focus on contexts that are innately perceived as threatening in the absence of conditioning or learning experiences (Davis, 1998). This consideration has involved research on changes in physiology, information processing, and behavior in rodents exposed to brightly lit open fields, which are innately dangerous contexts for nocturnal organisms. In a small, parallel series of studies, he has also studied responses in humans placed in dark rooms, which are innately dangerous contexts for diurnal organisms (Grillon et al., 1999).

Just as neuroscientists have begun to focus on innately dangerous contexts, researchers in other fields are examining a variety of inherently dangerous or fear-inducing stimuli. Interest in such stimuli is long-standing; many investigators have noted cross-species similarities in the behavioral, information-processing, and physiological changes that mammals undergo in response to dangerous or punishing stimuli (Darwin, 1998; Davis & Whalen, 2001; Rolls, 1999).

Among the numerous inherently dangerous stimuli available for study, threatening displays by conspecifics have aroused particular interest. Facial displays of emotion, particularly of anger, constitute principal signals of threat for humans and other highly social primates (Darwin, 1998; Haxby, Hoffman, & Gobbini, 2002). They are therefore optimal stimuli for research aimed at understanding social anxiety and Social Anxiety Disorder, both of which revolve around fear of interpersonal threat.

One important question that facial stimuli are useful for addressing is whether individuals with Social Anxiety Disorder respond differently than do nonanxious individuals when they view angry faces. For instance, an enhanced initial attention-orienting reaction to angry faces or a bias in the threshold for considering faces to be angry might characterize Social Anxiety Disorder. Either of these differences would represent anxiety-associated dysfunction in what Thompson (1994) terms emotional reactions. As we review later, studies in adults indicate that those with Social Anxiety Disorder differ from nonanxious peers in their attentional orienting to angry faces. It is also possible that initial reactions to angry faces or other social threat cues

are normal in Social Anxiety Disorder, and instead, the condition is characterized by abnormalities in the evaluation, monitoring, and modification of responses to such cues. Differences of this sort would represent dysfunction in emotion regulation.

It is important to note that the demonstration of any differences in socially anxious individuals' experience or regulation of emotional responses or the neural concomitants of these processes in no way suggests that they are static or primarily congenital in origin. Recent research documents the malleability of face emotion-processing skills. For example, these studies suggest that experiences during childhood, such as abuse and neglect, can alter an individual's threshold for detecting anger in a face (Pollak, 2003; Pollak, Klorman, Thatcher, & Cicchetti, 2001; Pollak & Sinha, 2002). Psychopathological states may similarly affect perception of threat cues; some evidence suggests that particular mood and anxiety disorders are associated with distinctive abnormalities in facial threat processing (McClure, Pope, Hoberman, Pine, & Leibenluft, 2003). For clinically oriented investigators with an interest in anxiety, an important task is to relate such differences in information processing both to functional aspects of neural circuits and to specific subtypes of anxiety, such as social anxiety. One approach to this task is to focus on Social Anxiety Disorder as it is currently conceptualized in *DSM-IV*. An alternative approach might focus on particular subtypes of the disorder that exhibit unique patterns of aggregation within families, comorbidity, or persistence over time.

The latter approach is consistent with evidence that biological substrates of different types of fear state vary considerably at fundamental levels. Recent advances in neuroscience have allowed investigators to conduct increasingly molecular studies of neural processing, thus, extending knowledge about brain circuits and even particular neurons that are engaged in highly specific anxious or fearful states. Thus, even though neurochemical and neurophysiological studies demonstrate clear differences in circuitry involved in learned and innate fears, molecular genetic evidence suggests that neither of these types of fear constitutes a monolithic category. Using genetic manipulation strategies, researchers have developed knock-out mice, which lack functional activity in genes that are central to the experience of highly specific types of fear. A manipulation that interferes with separation fears, for example, may not interfere with fear of inherently dangerous contexts. The effect that a manipulation has on a particular fear or anxiety depends not only on the gene that is targeted, but also on the organism's developmental stage at the time of the manipulation. For example, inactivation of

the gene for the 5HT_{1a} receptor in the mouse produces an increase in anxious behavior only when inactivation occurs early in life. Moreover, reactivation of this gene during adulthood has no effect on this type of behavior (Gross et al., 2002). Data from highly molecular neuroscience research thus dovetail nicely with behavioral findings in rodents and nonhuman primates to indicate that fear states in animals are heterogeneous. This parallels clinical findings in humans suggesting that clinical anxiety disorders are best conceptualized as related but distinct.

Anxiety and Information Processing

Alterations in information processing are consistently observed following presentation of both conditioned fear stimuli and inherently fear-provoking stimuli. In particular, fear-provoking stimuli reliably affect two cognitive processes: attention and memory. Recent studies in neuroscience demonstrate how the neural circuit depicted in Figure 12.3 participates in these processes when fear or anxiety has been evoked.

Attention

Because organisms possess limited capacity to process the many stimuli that they confront in the environment, they engage the cognitive and neural processes that constitute *attention* to help prioritize these stimuli. In particular, rodents, nonhuman primates, and humans selectively attend to stimuli that possess either punishing or rewarding properties. The neural circuitry devoted to the prioritization of perceptual information has been precisely elucidated in rodents and nonhuman primates (Davis & Whalen, 2001). This circuitry encompasses many of the key brain structures involved in fear conditioning, including the amygdala, posterior association cortex, and PFC. In particular, medial regions of the PFC, such as the anterior cingulate gyrus, play a central role in interactions between attention and emotional salience (Miller & Cohen, 2001). Many theories attempt to differentiate the stimuli, contexts, and other circumstances that engage distinct aspects of this circuit (Damasio et al., 2000; Davis & Whalen, 2001; Kalin, Shelton, Davidson, & Kelley, 2001; LeDoux, 2000). However, considerable disagreement persists on this issue.

Research in humans using “attention interference” tasks such as the emotional Stroop has demonstrated that anxiety-provoking stimuli affect attention. Attention interference tasks require study participants simultaneously to process nonemotional features of a stimulus (e.g., the color of ink in which a word is printed) and to ignore emotional aspects of the stimulus (e.g., the word’s emotionally laden

meaning). People tend to find it more difficult to ignore emotional aspects of stimuli that convey threat (e.g., the word “death”), which slows their color-naming performance (Williams, Mathews, & MacLeod, 1996). This tendency, which is greater in individuals with anxiety disorders and possibly those at risk for anxiety disorders, is presumably mediated by stimulus effects on attention allocation.

Effects of anxiety on attention have also been demonstrated in studies using visual search and attention orientation tasks. Visual search tasks involve locating nonemotional stimuli that are embedded in a field of emotionally evocative stimuli. Studies using these tasks have found that the presence of salient, emotional stimuli influence the speed at which a nonemotional target can be detected (Davis & Whalen, 2001; Hadwin et al., 2003; Mogg & Bradley, 1998). Studies using attention orientation tasks, which involve the processing of nonemotional stimuli that are either spatially or temporally contiguous to emotional stimuli, have yielded similar results (Mogg & Bradley, 1998, 2002). Much like attention interference, these effects have been shown to differ between individuals with and without anxiety disorders, including Social Anxiety Disorder (Mogg & Bradley, 2002; Mogg, Philippot, & Bradley, 2004). Additionally, when stimuli are presented briefly (33 msec or shorter exposure) and masked so that they cannot be consciously perceived, biases in attention orientation remain apparent, particularly in individuals with anxiety disorders (Mogg & Bradley, 1999; Mogg, Bradley, & Williams, 1995). This may reflect desynchrony between cortical and subcortical pathways involved in interactions between anxiety and attention, or it may reflect specific perturbations in the subcortical path extending directly from the thalamus to the amygdala (LeDoux, 1998).

One of the major controversies concerning the relationship between attention and anxiety relates to the direction of the association. Many theories suggest that underlying abnormalities in attention regulation predispose individuals toward anxious behavior and frank anxiety disorders (Clark et al., 1990; MacLeod et al., 2002; Mogg & Bradley, 2002). If confirmed, this hypothesis suggests a means for distinguishing among subgroups of children with anxiety disorders and identifying those subgroups at highest risk for anxiety. For example, among offspring of adults with an anxiety disorder, those who show particular orienting reactions to anxiety-provoking stimuli may be at heightened risk for developing a clinical disorder in the future. Although this hypothesis is plausible and enjoys some support (MacLeod et al., 2002; Merikangas et al., 1999), it is equally conceivable that increases or decreases in anxiety

might influence attention. Fear conditioning experiments demonstrate such an effect. Moreover, children who undergo traumatic experiences, whether they endorse anxiety symptoms or not, also demonstrate abnormalities in attention orienting to threat stimuli (Dalglish, Moradi, Taghavi, Neshat-Doost, & Yule, 2001). If this hypothesis were confirmed, it would suggest that abnormalities in attention bias are epiphenomena rather than risk or causal factors associated with later development of anxiety. Experimental studies in humans are just beginning to explore these alternative explanations for the consistent association between anxiety and attention abnormalities. Interestingly, the bulk of evidence to date suggests that abnormalities in attention for threat may represent risk factors for anxiety.

Memory

Both observational and experimental studies of humans have demonstrated that emotionally salient stimuli are easier to encode and recall than are neutral stimuli (Lang, Bradley, & Cuthbert, 1998; LeDoux & Muller, 1997; Phelps & Anderson, 1997). Recall of these two stimulus types also appears to involve different neurochemical systems. It remains unclear if these effects are driven primarily by differences in stimulus valence or in the degree to which different stimuli induce arousal. Some evidence suggests that negatively valenced stimuli, which can induce anxiety, are more easily encoded than positively valenced stimuli (Lang et al., 1998). However, it is difficult to equate positive and negative stimuli on arousal, and these findings may have emerged because the negative stimuli were more arousing than were the positive stimuli. The neural circuitry involved in the prioritization of stimuli for encoding in memory has been precisely delineated, and convergent findings across rodents, nonhuman primates, and humans indicate that the amygdala plays a central role in this process (Lang et al., 1998; Phelps & Anderson, 1997). However, in marked contrast to findings with regard to attention and anxiety, it has been difficult to demonstrate consistent relationships between clinical measures of anxiety and memory for negatively valenced stimuli (McNally, 1997). Some studies clearly document a memory advantage for negative stimuli in individuals with specific anxiety disorders, and other studies have found abnormalities in memory for face emotions in adults with Social Anxiety Disorder (Foa, Gilboa-Schechtman, Amir, & Freshman, 2000; Lundh & Ost, 1996; McNally, 1997). Most of these findings, however, have not been well replicated, and other data indicate that emotional memory perturbations are more closely associated with MDD than

with anxiety disorders (Blaney, 1986; McNally, 1997). In light of the well-documented influence of attention on memory, the failure to find a consistent memory advantage for threatening information in anxious individuals, who show enhanced attention for threatening information, is perplexing.

INFORMATION PROCESSING, SOCIAL ANXIETY DISORDER, AND COGNITIVE NEUROSCIENCE

The consistency and strength of associations between anxiety and information processing in rodents, nonhuman primates, and humans provide an excellent avenue for translational research that integrates basic and clinical approaches. Not only have behavioral effects been consistently observed in experimental paradigms relevant to anxiety, but the neural structures involved in these effects (see Figure 12.3) have also been identified in multiple laboratories using a variety of techniques. In addition, extensive rodent studies and emerging studies of nonhuman primates document developmental changes in functional aspects of this circuit that are relevant to anxiety (Coplan et al., 2001; Meaney, 2001b).

These bodies of research, in concert with findings of associations between human information processing and both the risk for and the presence of anxiety disorders, provide a solid foundation for the generation of precise hypotheses about the roles of specific neural structures in anxious behavior. With recent advances in fMRI, it has become possible to test such hypotheses, not only in human adults, but also in children and adolescents. Using fMRI, researchers derive an index of changes in blood flow that occur while study participants perform specific cognitive tasks. Differences in the magnetic susceptibility properties of oxygenated and deoxygenated hemoglobin provide the brain with its own endogenous contrast agent, such that increases in the flow of oxygenated blood to particular brain regions are reflected in patterns of activation in fMRI scans.

Although fMRI provides unusual opportunities to implement developmentally oriented translational studies, such research remains difficult to conduct. One major problem arises because neuroscience studies of human fear and anxiety have traditionally used a range of aversive stimuli, including electric shocks, noxious smells, grotesque pictures, verbal prompts, and pharmacological compounds. Many of these stimuli are too aversive to use with children. Others, such as abstract verbal representations of fearful events, may not evoke emotion as reliably in children as they do in

adults. Photographs of emotionally expressive facial displays have emerged as adequately evocative stimuli that are well suited for developmental research on emotion and information processing.

The use of facial emotion displays in such research followed observations that facial displays could induce emotion in observers across developmental stages, cultures, and species (Darwin, 1998; Nelson et al., 2002). Photographs of such displays have served as stimuli in numerous cognitive studies of healthy adults and children (Haxby et al., 2002; Monk, McClure, et al., 2003) that have demonstrated reliable interactions between emotion and information processing. Findings indicate, for example, that angry faces can engage attention and can interfere with performance on nonemotional tasks (Mogg & Bradley, 2002). Moreover, angry faces have been shown to be more memorable than other expressions under some circumstances (Lundh & Ost, 1996). These effects likely reflect influences of angry faces on the engagement of specific brain regions, such as the PFC, and associated aspects of information processing. Functional MRI studies document reliable activations of ventral and medial PFC regions by angry facial displays as well as activation of the amygdala during viewing of fearful faces, which may convey cues of indirect threat (Haxby et al., 2002).

Although these recent successes in neuroimaging have generated considerable enthusiasm, they are still far removed from the advances that they may eventually facilitate in the study and treatment of anxiety disorders. Ongoing research in other types of adult psychopathology provides some guideposts that translational research on anxiety disorders might follow to comprehensively capitalize on the strengths of fMRI techniques. Studies of Schizophrenia and Alzheimer's disease, for example, provide specific examples of one potentially fruitful path for fMRI research on pediatric anxiety, particularly pediatric Social Anxiety Disorder.

Neuroimaging research on both Schizophrenia and Alzheimer's disease has its foundation in studies of psychiatrically healthy individuals. In the case of Alzheimer's disease, research on healthy adults led to two important findings. First, it demonstrated that relevant cognitive paradigms could capture subtle memory abnormalities that occur early in the course of Alzheimer's disease (Bookheimer et al., 2000). Second, it showed that these paradigms reliably engaged regions of the brain, such as the hippocampus, that research in rodents and nonhuman primates had previously implicated in mnemonic functions. In the case of Schizophrenia, initial studies established cognitive paradigms sensitive to abnormalities in

working memory that are associated with both the disease and the underlying risk for the disease (Marenco & Weinberger, 2000). Subsequently, fMRI studies mapped the brain circuit encompassing dorsal components of the PFC that become engaged during working memory tasks (Callicott & Weinberger, 1999).

Such findings permitted the conduct of highly focused fMRI studies on patients that implemented cognitive tasks carefully chosen to target predicted deficits. This approach is potentially problematic, because differences in brain activation between patients and controls may result from one group's failure to properly perform the requisite cognitive operations, rather than from an underlying brain abnormality. To solve this problem, studies in both patient groups used tasks that included behavioral measures on which subjects' performance strategies could be explicitly monitored. Additionally, by using event-related and parametric fMRI research designs, researchers were able to assess brain activation during cognitive tasks relative to each subject's level of performance.

Functional MRI research on Schizophrenia and Alzheimer's disease has demonstrated abnormalities in brain activation during normal performance on tasks where patients and comparison subjects usually differ. For each disorder, such findings have led to hypotheses implicating inefficient engagement of particular brain regions in the genesis of psychopathology (Bookheimer et al., 2000; Callicott & Weinberger, 1999). These hypotheses have shaped recent ideas about risk, methods for early identification, and the role of genetics for both conditions. To successfully extend insights from clinical and cognitive studies in pediatric anxiety, similar groundwork must be laid in developmentally oriented fMRI studies.

Functional MRI studies in healthy adults initially demonstrated reliable activation in anxiety-relevant structures using face emotion-viewing paradigms (Haxby et al., 2002). These findings led to research using comparable paradigms in psychiatric populations. In these studies, adults with Social Anxiety Disorder, MDD, and PTSD each have been shown to exhibit abnormal activation in the amygdala during the viewing of face emotions (Rauch et al., 2000; Sheline et al., 2001). Moreover, such abnormalities have been linked to potential genetic susceptibility markers for each condition (Hariri et al., 2002).

The success of adult fMRI studies set the stage for extensions to studies of development and developmental psychopathology. Although such work is still in its infancy, initial studies have yielded evidence of some parallels in patterns of activation to threat cues between children and adults. Children with anxiety disorders, for example, like

adults with Social Anxiety Disorder, show evidence of enhanced amygdala activation during the viewing of some emotional facial displays (Thomas et al., 2001). However, some differences also have emerged between children and adults on these tasks. For example, one of the more consistent findings in adults is reliable amygdala activation during the viewing of fearful faces (Haxby et al., 2002). This finding has not been consistently replicated in children. In fact, some studies suggest that children show greater activation to neutral than to fearful faces (Thomas et al., 2001).

Recent developmentally oriented studies of face-emotion processing have also been limited by their lack of emphasis on behavioral data. Most studies either have used passive viewing tasks, which require no behavioral response, or have relied on relatively easy behavioral tasks, such as gender discrimination, where no developmental differences in associated cognitive processes are anticipated. These approaches deviate from the path outlined earlier for studies of Schizophrenia or Alzheimer's disease, which emphasized acquisition of fMRI data during the performance of a cognitive task expected to differentiate between groups.

Recent experimental psychology research lays the groundwork for informative fMRI studies in research on adolescent development and Social Anxiety Disorder. We provide two examples relevant to research on emotion reactions and emotional regulation. First, attention-orienting tasks, which measure an emotional reaction in the absence of subsequent implicit or explicit efforts at regulation, show promise for use in studies of Social Anxiety Disorder and development. Studies using such tasks have shown that angry faces reliably capture attention when they are presented in the context of nonemotional faces (Mogg & Bradley, 1998). This effect is thought to occur because angry faces more readily engage the amygdala and key components of the PFC, including the ventral or orbital frontal cortex and the medial or cingulate aspect of the PFC, than do other emotional faces (Haxby et al., 2002). Behaviorally, individuals with Social Anxiety Disorder, as well as those with other anxiety disorders, have been shown to exhibit behavioral differences on attention-orienting tasks (Mogg & Bradley, 2002). These behavioral group differences are also hypothesized to result from anxiety-associated decreases in the threshold for engaging the amygdala and ventral and medial PFC during tasks designed to elicit orienting to emotionally salient cues (Pine, 2001). Thus, tests of attention orienting, which have been shown to effectively capture one type of emotional reaction and activity within its associated neural circuitry, pro-

vide a measure of emotional reaction that is appropriate for studies of developmental psychopathology.

Second, other cognitive tasks that use face emotions as stimuli hold promise for use in developmental studies mapping neural circuits associated with anxiety and emotion regulation. These tasks require effortfully controlled attentional focus on nonemotional cues under conditions in which distracting, emotionally salient stimuli are present. Such tasks are clinically relevant because negative emotional displays from others are difficult for individuals with Social Anxiety Disorder to screen out, even when their attention is directed to performance of another task. This type of cognitive dysfunction is central to the genesis or maintenance of Social Anxiety Disorder. Indeed, most effective therapies for the disorder target problems with directing attention under states of high arousal, a basic emotion regulatory capacity. Tasks requiring attentional focus on nonemotional cues in the presence of emotional distracters are also developmentally relevant, because enhanced ability to control the direction of attention under states of high arousal represents one of the more robust changes associated with successful maturation from latency into adolescence and adulthood (Mischel, Shoda, & Rodriguez, 1989).

We have developed a cognitive paradigm that requires research participants to alternately direct their attention to their own emotional reaction to facial expressions and to either emotional or nonemotional features of faces that do not relate to their internal emotional responses. In healthy adults, such manipulations of attention during the viewing of evocative photographs have been shown to differentially engage the ventral and medial PFC (Monk, McClure, et al., 2003). Some controversy persists about whether the amygdala is also differentially engaged during such manipulations, with some studies indicating that it is and other studies suggesting that this structure becomes reliably engaged under both attention states (Dolan, 2002; Pessoa, McKenna, Gutierrez, & Ungerleider, 2002). In adolescents, however, these brain regions show differential modulation across types of emotional stimuli but not across attention states. These developmental differences are consistent with the idea that adults can modulate activity in relevant brain structures based on attentional demands, whereas such modulation in adolescents, whose neural structures are still immature, is driven by emotional content.

In light of findings from experimental studies, it appears likely that Social Anxiety Disorder is also associated with differential engagement of the amygdala and ventral and medial PFC during emotion response tasks such as atten-

tion orienting and emotion regulation tasks. Just as neuroimaging findings have laid important foundations for our understanding of Schizophrenia and Alzheimer's disease, the successful demonstration of differential neural engagement patterns in social anxiety could have considerable implications for future studies on underlying risk for and prevention of the disorder.

CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE WORK

In this chapter, we reviewed the literature on childhood anxiety disorders with a specific focus on Social Anxiety Disorder, which provides a model for integrating research from clinical psychopathology, developmental psychology, and cognitive neuroscience. Research on anxiety disorders from each of these perspectives has burgeoned in recent years, and the confluence of findings across fields holds promise for elucidating new prevention and treatment approaches for this type of psychopathology. The findings we reviewed form several themes that suggest directions for future study.

First, relative to other disorders, such as depression, anxiety disorders and their manifestations across development are broadly understudied. This reflects, in part, the historical belief that anxiety disorders constitute "mild" psychopathology. In light of recent evidence that childhood anxiety predicts a variety of negative outcomes, including the later development of Major Depressive Disorder (Pine et al., 1998), however, it has become clear that understanding anxiety disorders is critically important. In particular, research from a developmental psychopathology perspective would be useful for clarifying boundaries between normal and abnormal anxiety, for describing the paths that lead from early anxiety to either positive or negative outcomes, and for further explicating factors that confer risk for or protection against the development of pathological anxiety.

More specifically, recent research in developmental psychopathology suggests the need to consider alternative classification schemes for anxiety given advances in both basic and clinical neuroscience. This research shows that anxiety disorders are likely to represent the end result of a complex interplay among many risk factors operating across increasingly complex levels. For example, some risk factors may involve specific genetically based perturbations. These risk factors, in turn, may exert their effects through interactions either with other genes or with environmental factors. At a higher level, such effects are likely to shape underlying brain systems and their associated in-

formation-processing functions. Finally, whether or not perturbations in brain systems and associated information-processing functions ultimately manifest as clinical syndromes may depend on broader contextual influences on the developing organism. Given the complexity of these issues, our understanding of classification may change as our understanding of mechanisms advances. For example, children currently classified in the same broad category may ultimately be differentially categorized as we understand divergent mechanistic pathways to similarly appearing clinical syndromes. Conversely, children currently classified in distinct categories may ultimately be combined as we understand how core pathways can produce various clinical syndromes.

Ultimately, such efforts will require research on mechanisms through which risk factors influence phenotypic expression. Surprisingly, little is known about how various risk factors influence patterns of adaptation in developing individuals. In particular, offspring of adults with Social Anxiety Disorder, as well as other types of psychopathology, are at elevated risk for developing anxiety of their own. How the presence of this heightened risk, regardless of whether it eventually manifests as a disorder, influences children's and adolescents' negotiation and mastery of salient developmental tasks is poorly understood and worthy of research attention. For example, do youth at high risk for social anxiety by virtue of parental psychopathology differ from peers at lower risk in their patterns of attachment, peer relations, or conceptions of self? Further, are such differences evident in individuals who prove resilient to anxiety despite their high-risk status?

Additionally, much existing research has focused on individual risk factors in isolation. Integrative studies that approach risk from multiple perspectives simultaneously would provide a more accurate picture of the complex interplay among genetics, neurobiology, family environment, peer relations, and other influences. Recently, studies combining genetic approaches with neuroimaging techniques have begun to emerge in the literature, offering one example of how such integrative research might manifest.

Second, research in clinical psychopathology strongly suggests that the anxiety disorders constitute a set of related but distinct pathologies. Although, in general terms, all of these disorders involve perturbation in the capacity to regulate anxious states, it appears likely that specific pathophysiologic profiles are associated with the particular patterns of maladaptation that characterize individual disorders. Additionally, data from the developmental psychology literature underscore the fact that anxious states are

pervasive and common across the life span. Consequently, the line between normal and abnormal anxiety is difficult to identify, particularly at the level of behavior, where a normal, transient anxiety state can closely resemble states that occur in the context of an enduring disorder. Further complicating the distinction of typical from pathological anxiety is the variability across developmental stages in the manifestations of anxiety that are considered normal. It is therefore important that studies be conducted that further illuminate the distinctive pathophysiology of each anxiety disorder across development, with an eye to identifying markers of risk and optimal pathways for treatment. Such efforts will require a bridging of perspectives from clinical and basic sciences.

For example, conceptualizations of clinical characteristics may advance if they describe behaviors in a fashion that is amenable to research in experimental psychology and neuroscience. This will require a more precise specification of behavior than currently available in the clinical literature. Current clinical conceptualizations describe relatively broad perturbations in cognition, such as enhanced vigilance in anxiety. To facilitate integration with psychology and neuroscience, future conceptualizations will need to describe in more detail the precise circumstances under which attention is perturbed in the anxiety disorders.

Finally, researchers in other clinical areas, such as Schizophrenia and Alzheimer's disease, have begun to develop paradigms that elegantly bridge the gap between basic science and clinical utility. Anxiety disorders are primed for similar translational work that capitalizes on converging findings across multiple diverse areas of research. In particular, fMRI studies provide a promising avenue for integrating the provocative data that have emerged recently from work on fear conditioning and extinction across different species, threat cue processing in humans, and genetics. These disparate areas of study each provide important information regarding the processes involved in emotion regulation that, taken together, could eventually revolutionize the treatment of anxiety.

SUMMARY AND IMPLICATIONS 532

REFERENCES 533

Antisocial behavior is disruptive to the individual, to family and friends, and to the community at large. It is for this reason that adults attempt to reduce antisocial behavior in efforts to socialize children. When such efforts fail, parents and caregivers often seek help, such as in mental health clinics. It is estimated that 50% to 75% of all referrals focus on behavior problems in children (Kazdin, 1987, 1993).

Among all the child adjustment problems, the literature on the study of child and adolescent antisocial behavior is the most abundant and historically rich (see Costello & Angold, 2000). Initially, thinking about the origins and solutions to antisocial behavior in children and adults was largely philosophical and speculative. Plato's *The Republic* (Hamilton & Cairns, 1973), written c. 360 B.C., provides a detailed sociopolitical system for promoting the character of youth so as to minimize behaviors thought to detract from a harmonious state and promote behaviors conducive to community living.

A critical piece to the philosophical puzzle is whether antisocial tendencies are innate or are acquired through the vagaries of social living and misguided socialization efforts. Hobbes, in *Leviathan* (Rogers & Schulman, 1651/2003), assumes that antisocial tendencies are innate, and consequently, prosocial behavior conducive to group living required careful training and socialization. In contrast, in his

treatise on *Emile*, Rousseau (Friedlander, 1762/2004) proposed that children by nature are prosocial but misguided efforts by adults transform goodness into antisocial behavior. The implication is that if children were raised in a natural, benevolent state, many problem behaviors would be minimized or eliminated. John Locke (Anstey, 2003) proposed a position that could be seen as neutral to these two perspectives, assuming that children were a tabula rasa with respect to good and evil and that all behaviors were simply outcomes of experience and learning. This has often been associated with learning theory accounts of individual differences. A fourth perspective, attributable to Darwin (1991), is that individuals actively learn behaviors that promote survival of the individual and the species. Thus, individuals come to social living with a propensity to learn some behaviors over others, based on biologically based biases in learning. The key is that behaviors are more easily learned when they function to increase the survival of the individual and genetically related kin. As we shall see, the fourth perspective is a compelling philosophical framework for thinking about the development and ecology of antisocial behavior.

Not until recently have the tools and strategies of science been applied to understanding human behavior in general and antisocial behavior in particular. There is a clear sense that empirical formulations of antisocial behavior

are progressing in respect to replication as well as validation in the context of intervention (Dishion & Patterson, 1999). However, in considering the impressions of the earliest professionals charged with the responsibility of managing antisocial children, one wonders just how much progress has been made. For example, consider the following statement by Adams (Carpenter, 1970, p. 15), who was responsible for managing antisocial youth in a reformatory school in nineteenth-century England:

Sergeant Adams states before the Select Committee of the Lords, that of the 100 prisoners whom he has to try every fortnight, from 16 to 40 are boys; some even of the age of 7; a few of 8, and a great number of 9 and upwards; of these children the offenses are, for the most part, of a pilfering description, to which the young children are tempted by older persons. "A large portion of these poor children," says Mr. Adam, "are wholly and entirely without friends and relations of any kind; others have profligate parents who neglect them; and almost all are quite uninstructed in religious, moral and social duties. I should say the evil is far more deeply seated than in the natural disposition of the children themselves. I do not think they are naturally worse than other children themselves; but that these offenses spring from the want of proper moral and religious education and in the want of proper friends to attend to them."

From Sergeant Adams' perspective, many antisocial youth are early starters, often male, have poor peer relations, and come from families that could be described as disrupted parenting. Sergeant Adams would minimize the contribution of genetic factors in favor of environmental effects.

The early work on antisocial behavior was largely concerned with managing children who broke the law and required remedial, or at least custodial, intervention. In the twentieth century, however, psychologists entered the intellectual landscape. Healy (1926) published the first psychologically oriented treatise theorizing on the etiology and treatment of antisocial behavior. His thinking, heavily influenced by the psychodynamic theory of that time, emphasized internal, intraindividual factors in the etiology of crime, especially lack of cognitive abilities (i.e., "dull thinking"), and secondarily, problematic parenting. Even though he notes that peers are most often a proximal factor in the commission of antisocial acts (nearly every case reviewed!), in his mind, peers were unlikely to be a significant etiological factor. His thinking was that failure to care about mores and to inhibit antisocial behaviors was an intrapersonal characteristic that could only be solved by treating the individual. Despite this individual orientation, Healy was also an empirical pragmatist. Ten years later, he

published quasi-experimental findings on outcomes associated with two different correctional practices in Chicago and Boston, noting that about 61% of the males and 46% of the females would eventually recidivate (Healy & Bronner, 1936). Rates of recidivism, he noted, vary as a function of the correctional strategy used. In Chicago, where institutionalism was the dominant strategy, failure rates reached 70%, whereas in Boston, where foster care was the pervasive practice, recidivism was only 27%. These writers, aware of the limitations of quasi-experimental strategies, tentatively suggested that institutionalization may not be the ideal solution for diverting lives of crime for antisocial youth. This suggestion has gone largely unheeded, despite the results of later studies using random assignment (Chamberlain & Reid, 1998; Eddy & Chamberlain, 2000).

The continued application of psychodynamically oriented treatments for antisocial children and adolescents generally did not produce satisfactory results. Influential practitioners and theorists such as Redl and Wineman (1951, 1952) reported dramatic failures in their efforts to treat antisocial youth. These failures were followed by extensive reformulations of psychoanalytic theory and the introduction of the attachment construct and ethological theory (Bowlby, 1969). The pessimism was supported by empirical findings: Nothing was effective when working with antisocial children (Levitt, 1957, 1971).

The *internal trait* model was the overarching paradigm that integrated these theories and interventions designed by psychologists and criminologists. From this perspective, the traits are intraindividual dynamics whose prime characteristics are stability and continuity of behavior. Indeed, the stability and continuity of antisocial behavior was such that the use of the term *trait* was empirically justified (Loeber & Dishion, 1983; Olweus, 1979). A trait model (Goldberg, 1994), however, contained no information about mechanisms of change. The trait models are indeed empirically based but fall short of identifying mechanisms that account for stability and, more important, provide no guidance as to how to prevent or reduce antisocial behavior in children and adolescents. Not until the 1970s and 1980s was it understood that there is an important link between understanding a development process and selecting the appropriate prevention and treatment.

Considerable progress has been made during the past 20 years in providing an empirical account for antisocial behavior in children and adolescents. These studies represent a fusion of the seminal works by Lee Robins (1966) and other sociologists (see review by Loeber & Dishion, 1983), the life course perspective of Glen Elder (1985), measurement theorists (Campbell & Fiske, 1959; Cronbach &

Meehl, 1955), and the careful observation research of criminologists (e.g., McCord, McCord, & Howard, 1963) and developmental (e.g., Dawe, 1934) and clinical psychologists (e.g., Patterson, Littman, & Bricker, 1967; Raush, 1965). These investigators brought forth a strong focus on measurement, longitudinal designs, and a consistent pattern of findings of environmental correlates and predictors of antisocial behavior. More recently, investigators have moved to what we refer to as a *process account* of antisocial behavior, which provides an analysis of the etiological dynamics of growth and desistance over time. In this way, the new wave of studies in the past 2 decades represents a strategy of linking longitudinal research with intervention studies, where developmental processes are targeted in the efforts to reduce problem behavior, but also to test hypotheses regarding the mechanism of change.

At this juncture, we are able to provide a stronger proposal for the etiology of antisocial behavior in children and adolescents, compared with our previous review (Dishion, French, & Patterson, 1995). In some ways, the picture has simplified, especially with respect to what we know about the nature and timing of major environmental effects, biological underpinnings, and dynamic and functional processes as they unfold over time. To begin, however, it is necessary to consider what we now know about the developmental variation and changing form of antisocial behavior from early childhood to late adolescence.

DEVELOPMENTAL PATTERNS

All forms of *antisocial behavior* share a common characteristic: They are experienced as aversive, disruptive, or unpleasant by those who are victims or those who are close to the youth. During adolescence, new behaviors are added, such as drug use and sexual activity. These behaviors are often thought of as “victimless.” Adolescent substance use and precocious sexual behavior are known to lead to problematic adult adjustment and also to be a source of conflict between adults and youth. To address this heterogeneity, the more general term of *problem behavior* is used. Figure 13.1 provides an overview of the kinds of behaviors that are experienced as aversive by victims or deemed problematic by adults from early childhood to late adolescence. The perspective of the current *Diagnostic and Statistical Manual of Mental Disorders (DSM)* is reflected in Figure 13.1 as well.

Several investigators recognized distinct types of antisocial behavior and conduct problem children (e.g., Jesness, 1977; Patterson, 1982; Quay, 1993). Our first efforts to observe antisocial children and their families suggested that

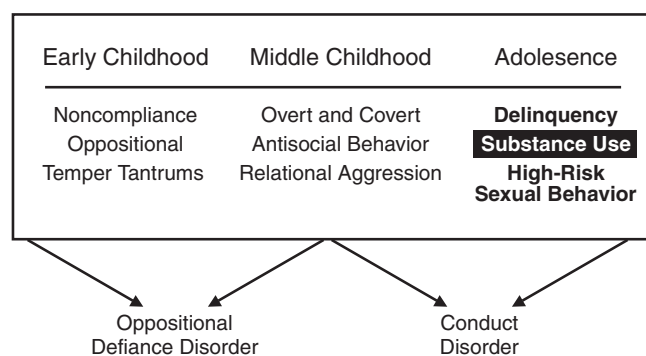

Figure 13.1 The labeling of problem behavior through childhood to adolescence.

interactions observed in the homes of youngsters referred primarily for aggression were fundamentally different from those referred for stealing (Patterson, 1982). The differences were detectable in the observed behavior of both the child and the parents. Considering findings such as these as well as a meta-analysis of child referral problems, Loeber and Schmalting (1985) introduced the terms *overt* and *covert* antisocial behavior, a taxonomy that has stimulated a great deal of research over the past 2 decades (e.g., Hinshaw & Anderson, 1996; Hinshaw, Lahey, & Hart, 1993; Liao, Barriga, & Gibbs, 1998).

If we take a psychometric approach to conceptualizing antisocial behavior, we might consider covert and overt antisocial behavior as different behaviors within an overall trait for being antisocial (see Dishion, French, et al., 1995; Patterson, Reid, & Dishion, 1992). This would be consistent with problem behavior theory (Jessor & Jessor, 1977) in which adolescent problem behaviors are considered to be one overall syndrome. The findings from the Oregon Youth Study provided support for such a perspective. Using structural equation modeling, we found a correlation of 1.0 between the two constructs (Patterson, Reid, et al., 1992). Obviously, boys who engage in high rates of overt antisocial behavior also engage in high rates of covert antisocial behavior. The correlation speaks to the fact that by early adolescence, both forms belong to the same general class of behaviors.

Within the class of aggression, distinctions can also be made. The most critical appears to be that between *reactive* and *proactive* aggression in children (Dodge & Coie, 1987). Again, reactive and proactive types of aggression are highly intercorrelated (Dodge & Coie, 1987; Poulin & Boivin, 2000b). A developmental analysis of proactive and reactive aggression suggests unique antecedent conditions, sequelae, and functional mechanisms (Crick & Dodge, 1996; Poulin &

Boivin, 2000a; Price & Dodge, 1989; Pulkkinen, 1996; Vitaro, Brendgen, & Tremblay, 2002).

More recently, the concept of relational aggression has been put forward, fitting best within the realm of covert antisocial behavior (Cairns & Cairns, 1994; Crick, 1996; Crick & Bigbee, 1998; Crick et al., 1997; Grotjeter & Crick, 1996; Underwood, 2003). Relational aggression is directed to peers and involves behaviors such as spreading rumors, ostracizing, and purposely manipulating relationships to the detriment and pain of a recipient.

As can be seen in Figure 13.1, the developmental sequence from overt to covert behaviors can be mapped onto the *DSM-IV* nomenclature of Oppositional Defiant Disorder and Conduct Disorder. However, relational aggression, to date, has no clear home in this or the *International Classification of Diseases* diagnostic system.

In contrast to our earlier review (Dishion, French, et al., 1995), we see the value in making distinctions between highly correlated but topographically unique forms of child and adolescent problem behavior. As a heuristic model, in this review, we group reactive forms of aggression and antisocial behavior as overt and antisocial behaviors that often involve peer coordination and avoidance of adult detection as covert. As we shall see, the critical issue is the developmental and relationship context in which these behaviors emerge. Studies show that overt and covert forms of behavior come into play at very different developmental stages and are controlled by very different functional mechanisms and social agents. Building a model of child antisocial behavior requires an intimate knowledge of these unique developmental patterns.

Overt Antisocial Behavior

During the first 2 years of life, it is not unusual for children to be oppositional and difficult to control at times. Tremblay (2000) has argued that if 2-year-olds were physically as large as adults they would be dangerous, as they do hit and become quite angry. By middle childhood, the range of child behavior, the places in which they occur, and their form and function become more complex.

Given that children begin to engage in aggression and oppositional behavior as toddlers, maternal reports would seem relevant to understanding early developmental trajectories. Systematic study of maternal reports in a large Canadian cohort, in fact, reveals a clear decrease in these behaviors from ages 2 to 11 (Tremblay, Masse, Pagani, & Vitaro, 1996; see Figure 13.2). The findings are consistent with those from mothers' longitudinal ratings of overt antisocial behaviors cited earlier. Longitudinal studies by

Figure 13.2 Decreases in aggression in early childhood. Adapted from Tremblay et al., 1996.

Cairns, Cairns, Neckerman, Gest, and Garipey (1988) found a similar decrease in physical aggression between ages 10 and 18 years, based both on teacher ratings and self-report data. Tremblay et al. (1999) also found a decrease in teacher reports of physical aggression for boys from 6 to 15 years of age. The large-scale Dutch longitudinal study of maternal ratings of children ages 5 through 18 years showed negative slopes for both boys and girls on aggressive behavior (Stanger, Achenbach, & Verhulst, 1997).

Of particular interest in the work of Tremblay and his colleagues is the finding that during the elementary grades, there are few if any new cases of physical aggression added to the cases identified by grade 1 (e.g., a low false-negative error; Nagin & Tremblay, 1999). The findings were essentially replicated in the longitudinal study of at-risk boys from grades 1 through 5 (Patterson & DeGarmo, 1997). Only 1.5% of the boys in the normal range at grade 1 had moved to a clinical range for overt antisocial behavior by grade 5. Again, this suggests a very low false-negative error in predicting later adjustment. Evidently, the most severe problems associated with overt antisocial behavior are in place before grade 1, and few new cases are added after that. The fact that there are few new cases added suggests that the preschool, familial training phase is critical in understanding the emergence of aggression in young children.

There is a strong negative slope describing the relation between the age of the child and the frequency of reported overt forms of antisocial behavior. This relation holds across teacher, parent, and observers as assessment agents. The consistency of the developmental findings demands an explanation. Why is there a drop?

We hypothesize that as children age, adults become increasingly vigilant and attentive to all forms of overt anti-

social behavior and effectively reduce such behavior through punishment or by reinforcing prosocial alternatives to aggression (asking, waiting, sharing, turn taking, etc.). The term reactive aggression also provides a clue. Children who initially engage in aggression are essentially reactively coercive, using such tactics as crying, whining, hitting, and persistence to reduce adult socialization efforts or aversive intrusions by peers. Fortunately, over time and through socialization, children become more regulated and planful in their response to their social environment. They become less reactive to aversive experiences, and if they do not, they pay the consequences of poor peer relations and social rejection (Coie & Kupersmidt, 1983; Dodge, 1983; Poulin & Boivin, 2000a).

The picture is more complex, however. As children desist in some forms of antisocial behavior, they pick up new behaviors. For example, proactive aggression emerges in middle childhood (Poulin & Boivin, 2000b), which appears be a consequence of involvement with other, aggressive peers. Snyder (Snyder, Reid, & Patterson, 2003) hypothesized that the effect of these changes in adult and peer contingency might drive aggression “underground.” Some children may simply learn to avoid detection and, in so doing, also avoid the negative consequences supplied by adults. In this sense, they become more regulated but also, unfortunately, more deviant as well. The child simply shifts to more covert forms.

Covert Antisocial Behavior

As defined earlier, covert antisocial behavior includes aggressive acts that seem designed to avoid detection. For example, proactive and relational aggression can be seen as a covert form of antisocial behavior. As such, forms of covert antisocial behavior are detectable in middle childhood (age 6 years), increasing slowly during late childhood, then accelerating at early adolescence. Of particular relevance for socialization theory is the fact that throughout the developmental course, growth in overt and covert behaviors have diametrically opposite slopes. After the age of 2 years, the slope for overt forms is essentially negative through adult years. Developmentally, covert behavior begins with a neutral slope and then shifts dramatically to positive during early adolescence. An analysis of maternal ratings of boys' covert antisocial behavior is summarized in Figure 13.3. Based on data from a large prevention sample ($N = 204$), the ratings covered the interval from grades 1 through 5 (males; Patterson & Yoerger, 1997). Similarly, the longitudinal analyses of maternal ratings for grades 1 through 5 showed a nonsignificant positive slope (Patterson & Yoerger, 2002).

Figure 13.3 Changes in covert antisocial behavior for three groups of LIFT buys. Adapted from Patterson and Yoerger, 2002.

It becomes difficult, therefore, to really know whether there is an overall decrease in aggression from age 2 years through adolescence. It is conceivable that as overt forms decrease, adding the growth in covert behavior would generate a total output score that is closer to a zero slope. Maternal ratings from a large prevention trial sample offer some support for the idea that total output may remain stable from one grade to the next for grades 1 through 5 (Patterson & Yoerger, 2002).

It would be expected that measures of overt antisocial behavior during childhood would provide low-level but significant predictions of adolescent and adult crime. For example, in a systematic analysis of six longitudinal data sets, overt forms of antisocial behavior predicted both adolescent physical aggression and covert antisocial behavior (Broidy et al., 2003). It is noteworthy that female adolescent antisocial behavior is not predicted by early overt antisocial behaviors in these six longitudinal data sets.

This raises the question as to the most significant predictors for adolescent and adult crime. For example, it could be that the more severe forms of antisocial behaviors were the best predictors. We were pleased to find that such weighting schemes were not necessary. In fact, the total frequency of relatively trivial forms of antisocial behavior is strongly correlated with more severe forms of delinquent behavior. For example, in the Oregon Youth Study (OYS) by Capaldi and Patterson (1996), the frequency of self-reported trivial crimes correlated .63 with the frequency of self-reported severe crimes. Also, youth who commit more frequent crimes are at significantly greater risk to commit violent crimes. For example, if the adolescent had been arrested three or more times, the likelihood was .47 that he would commit a violent crime. The comparable figure for Farrington's (1991) London cohort was .49. Frequency, of

course, suggests versatility (Loeber, 1991; Loeber, Green, Keenan, & Lahey, 1995; Loeber et al., 1993). Initially, we had thought that perhaps the more severe forms of overt or covert behavior would serve as better predictors.

Delinquent Behavior

Delinquent behaviors are an important subset of antisocial (overt and covert) behavior. What makes them unique is that society considers them to be illegal. What makes this complex is that the definition of what is illegal can, and does, change over time. Many delinquent behaviors also have a victim. Examples include robbery, theft, burglary, and vandalism. Other behaviors are statutory, such as substance use and sexual precocity. Here, victim's status is unclear, but technically, our definition of antisocial behavior requires a victim. Thus, substance use is included in this review only as it relates to the etiology and course of antisocial behavior. It is clear that there are youth who engage in these behaviors but who are not involved in antisocial behavior (Dishion & Loeber, 1985; Loeber, 1988), and peer and family dynamics reflect this difference (Dishion & Loeber, 1985), in that youth who use substances and are not antisocial are generally exposed to less risk within the family and peer domains.

If one focuses narrowly on illegal, criminal, or delinquent behavior, it is clear that there are enormous differences in the age at which individuals first engage in these behaviors. There are 7-year-olds who are arrested; others are arrested in adolescence (Moffitt, 1993; Patterson, Crosby, & Vuchinich, 1992; Robins, 1966). Generally, there is positive growth in criminal behavior during adolescence (Achenbach & Edelbrock, 1979), which peaks somewhere between 16 and 18, depending on the context and behaviors included in the study. Following the peak is a relatively rapid decrease in illegal behavior, forming a negative quadratic function. This is often referred to as the age-crime curve (Gottfredson & Hirschi, 1990). One of the most interesting findings from the OYS sample was the data showing that 18% of youth arrested as adults had no prior history of arrests; some of the males waited until adult status to commit their first crime (Patterson & Yoerger, 2002).

The developmental trends in criminal behavior among youth and young adults are likely to be obscured by trends in *learning to avoid detection*. By definition, teachers and parents probably have only a limited awareness of the frequency of covert acts. For example, early-onset boys in the OYS show the expected decrease in police arrests starting at around age 17 years. During that same interval, however,

the early-onset boys self-reported a fourfold increase in index crimes (Patterson & Yoerger, 1993). According to the *learning to avoid detection* hypothesis, this may simply reflect the fact that after several arrests, the boys improved their skills in learning to escape police detection. Farrington, Jolliffe, Hawkins, Catalano, Hill et al. (2000) found that the probability of being referred to juvenile court actually decreased as a function of frequency of self-reported crimes. Again, this suggests to the present writers that the more prolific offenders had learned to avoid detection.

Criminology's study of specialization would be one well-known alternative to the frequency hypothesis. Are there numerous paths to each specialized crime (e.g., safe-cracking, mugging, arson)? Farrington's (1991) analysis of the London cohort study found no tendency for males in the sample to specialize in property or person crimes.

We hypothesized that understanding the overt-to-covert sequence is absolutely essential in planning prevention studies. We also hypothesized that measures of the overt-covert sequence should provide a useful basis for predicting later juvenile and adult crime. If the model includes only measures of overt antisocial behavior, the prediction model will be weakened. It is also assumed that a model based only on measures of covert antisocial behavior assessed during adolescence will be very effective in predicting adolescent offending but weak when predicting adult crime. The reason for this is that both the early- and late-onset boys are heavily involved with deviant peers, as shown in Patterson and Yoerger (1993, 2002). The OYS data show that most of the late-onset boys score high on covert scores but as adults become desistors (Patterson & Yoerger, 1997). When predicting adult crimes, the most effective prediction model would include the sequence of first overt and then covert (Broidy et al., 2003; Patterson & Yoerger, 1997, 1999).

Trajectories that are high on both overt and covert forms would also be characterized by high overall frequencies. Both sets of information would predict early onset for delinquency. Loeber (1991; Loeber et al., 1993, 1995) showed that indeed it is the case that simply combining overt and covert generates significant predictions. As yet, no one has compared the relative efficiency of using childhood frequency measures of overt and covert, adolescent measures of covert, and various sequential patterns.

Age of onset for delinquent behavior occupies a salient place in the traditional literature of criminology. Robins (1966) noted that boys arrested at a young age had more serious outcomes than those arrested in later adolescent years. Several decades of studies firmly establish the correlation between early onset and total frequency of later ar-

rests (Loeber & Farrington, 2000; Patterson, 1996; Patterson, DeBaryshe, & Ramsey, 1989; Patterson & Yoerger, 1997). It is, therefore, not surprising that the earlier the onset, the greater the risk for chronic arrests. For example, in a study of the OYS, Patterson and Yoerger (1993) found a correlation of .93 between the age of onset of first arrest and the likelihood of a fourth arrest. Given early onset (arrest before age 14 years), the likelihood of three or more juvenile offenses was .76 (Patterson, Forgatch, Yoerger, & Stoolmiller, 1998).

Several writers have emphasized the utility of differentiating between early- and late-onset delinquents (Moffitt, 1993; Patterson et al., 1989; Robins, 1966). In the OYS studies, about half of the police arrests involve early offenders and half involve late offenders. In the Dunedin studies, about 10% of the sample were defined as early onset (life-course-persistent) and 25% as late onset (adolescent-limited). The prevalence rates for the Oregon sample were 26% and 29% for early and late, respectively. The differences in prevalence for the early starters reflect the fact that the Oregon sample consisted of at-risk families living in high-crime areas, whereas the Dunedin studies were based on carefully drawn birth cohorts. Although the Oregon and New Zealand studies agree on the importance of differentiating the two paths, they are in almost complete disagreement as to the mechanisms that produce these outcomes. The causal mechanism models are reviewed in a later section.

It is now understood that the commission of antisocial acts usually precedes the commission of delinquent acts by several years. For example, data from three samples showed that 10% to 25% of the sample self-reported serious and violent behavior by age 10 years (Loeber & Farrington, 2000). Data from the OYS were used to test the hypothesis that boys from disadvantaged families and inept discipline practices would be among the first to be arrested (Patterson, Crosby, et al., 1992). Both variables made significant contributions to early arrest. It was assumed that a composite (overt plus covert) measure of antisocial behavior assessed at age 10 years would be the major predictor. In effect, the contribution of inept discipline to age of first arrest would be mediated by the antisocial variable. In the event history analyses, as predicted, when the trait score was introduced into the regression analyses, the relative contributions of discipline and socioeconomic status became nonsignificant. The highly significant contribution of the antisocial trait score showed that the more antisocial the boy, the earlier his first arrest.

In that study, the findings from the distribution of hazard rates carry a particularly interesting piece of informa-

Figure 13.4 Distribution of hazard rates for high- and low-antisocial boys.

tion. The hazard rate describes the percentage of boys' first arrest at a particular point in time. Figure 13.4 compares the distribution of hazard rates for boys scoring above the median on the antisocial composite with those scoring below the mean for the antisocial trait. It can be seen that at age 10, about 5% to 6% of the boys were involved in their first arrest. The peak risk for this group occurred at age 13, when 23% of those not previously arrested were arrested.

Of particular interest is the distribution of hazard rates for boys below the mean for antisocial behavior (i.e., late-onset boys). At ages 14 and 15, there was a steady increase in risk for first arrest. These findings describe the trajectories for the late-starter group. In the Oregon model, the late-starter group tends to be less antisocial as children and are at increasing risk for a first arrest after the age of 15.

Moffitt, Caspi, Harrington, and Milne (2002) followed up the Dunedin sample through age 26 to demonstrate that, as adults, the early-onset group was more at risk for substance use, mental and personality problems, financial and work problems, and violent crime. The late-onset group also tended to be at elevated risk for most of these problems, but at less extreme levels. Moffitt et al. assume that the late-onset group is very near to normal levels in terms of childhood risk variables: "However, because their pre-delinquent development was normal and healthy, most young people who become AL (adolescent limited, late onset) are able to desist from crime when they age into real adult roles" (p. 280).

We hypothesize that developmental and relationship dynamics account for the differences in adult outcomes observed between early- and late-starting delinquent adolescents. In fact, we see the distinction between the two groups as one of gradations and the groups unlikely to be unique

taxonomic groups. For example, DiLalla and Gottesman (1989) compared persistent and transitory offenders and found that the latter were better adjusted than persistent offenders. However, it was also the case that the transitory offenders were less well adjusted than were the nonoffenders. Findings from the OYS were consistent with the hypothesis that the late-onset group was less deviant than the early-onset group but more deviant than nonoffenders.

In our previous review, we introduced the “marginal deviation hypothesis,” which was essentially a statement of equifinality, especially for late-onset delinquent behavior (Dishion, French, et al., 1995). Simply put, a variety of social and biological circumstances (e.g., temperament, academic problems, divorce, stepparenting) can be linked to engagement in peer groups that support growth in specific forms of problem behavior. Indeed, for this group, having positive peer relationships may be part of the problem. Indeed, a composite rating (peers, teachers, parents) showed that the late-onset group had better relationships with peers than did the early-onset group. As noted in a later section, the evidence suggests that early onset is correlated with more pervasive family dysfunction, and late onset and persistence among early starters is explained by the emergence of peer dynamics in adolescence (Patterson & Yoerger, 1997, 2002). Despite the diverse etiological circumstances of each developmental pattern, it is reasonable to conclude that late-onset delinquents are anything but normal; their problems are simply less severe. This may in part be a function of positive aspects of their socialization, in particular the development of a modicum of self-regulation and control, which enables the eventual formation of positive work and relationship skills.

Although the topic of causal mechanisms is discussed in a later section, it should be noted here that the critical variable determining membership in early, late, or nonoffending trajectories is a time-dependent measure of involvement with deviant peers, as shown in the studies by Patterson and Yoerger (1997, 2002). Several studies now show that bursts in involvement in deviant peers is associated with increases in substance use (Dishion & Medici Skaggs, 2000) and delinquent behavior (Elliott & Menard, 1996; Patterson & Yoerger, 2002). Although many theorists emphasize the role of peers (e.g., Elliott, Huizinga, & Ageton, 1985; Moffitt, 1993; D. W. Osgood, Wilson, O'Malley, Bachman, & Johnson, 1996; Warr, 1993), we specifically target the social interaction dynamics and behavior contingencies as critical for understanding the emergence and progression of antisocial behavior in adolescence (Dishion, Spracklen, Andrews, & Patterson, 1996). The added emphasis on rela-

tionship dynamics, we hope, is useful for the design and execution of interventions that reduce antisocial behavior.

Trajectories

The analysis of developmental patterns was often described as an analysis of “pathways” (e.g., Loeber, 1988). The idea is that there are unique events that unfold in an orderly sequence that lead to a final developmental outcome. This appealing metaphor was just that until recently, when the advances in quantitative methods allowed for estimation of person-centered longitudinal patterns that are now referred to as *trajectories* (Muthén & Muthén, 2000; Muthén & Shedden, 1999; Nagin, 1999).

These quantitative innovations have led to several interesting trajectory studies, confirming the points made earlier. For example, Shaw, Gilliom, Ingoldsby, and Nagin (2003) identified longitudinal trajectories of aggressive behavior that were highly predictive of school-age conduct problems. The work by Lacourse, Nagin, Tremblay, Vitaro, and Claes (2003) examines developmental trajectories leading to delinquency and violence in adolescence. Most analyses of developmental trajectories produce a high stable group and a consistently prosocial group. The remaining groups vary with respect to developmental patterns. For example, the study by Wiesner and Capaldi (2003) produced six different trajectories with the sample of 204 OYS males. These elegant statistical models will certainly become the wave of the future. As is typical, new quantitative models provide a basis for seeing new complexities in establishing trajectories that may depend on measurement issues, sample size, the kinds of causal predictors entered into the analysis, and the developmental period under consideration. A simple case in point is that arrest, self-report, teacher report, and parent report data may provide unique perspectives on the number and shape of developmental trajectories in antisocial behavior, as found in the study by Cairns and colleagues (Cairns, Cairns, Neckerman, & Garipey, 1989). Moreover, the trajectories for male and female youth may be distinct, as indicated by less of a connection between overt antisocial behavior and the later emergence of covert behavior problems in girls (Moffitt, Caspi, Rutter, & Silva, 2001).

An often neglected issue in studying trajectories is the explanation of persistence and desistance. In Loeber's (1982) reanalysis of conviction data, both suggest that the actual shape of the trajectory curves vary as a function of age of onset. For example, in examining data sets based on official records, Patterson and Yoerger (1993) found that

boys who begin their arrest career by ages 10 through 12 years had a unique shape to their trajectory. The curve was initially flat or even positive and then dropped steadily to young adult years. However, the boys first arrested at ages 14 to 18 years started somewhat lower and showed an immediate precipitous drop at young adult years (Patterson & Yoerger, 1993).

Desistance is particularly interesting. An analysis of the OYS longitudinal data set showed that at grade 4, 49 boys scored at the 75th percentile on a composite measure of overt antisocial behavior. Of these, 22 failed to become involved in growth for covert behavior over the ensuing 8 years (Patterson & Yoerger, 1999). From our perspective, this failure implies that they were not involved in deviancy training provided by deviant peers (Patterson, Dishion, & Yoerger, 2000), or that they actively avoided deviant peers and their influences to persist on a normative trajectory (T. Gardner & Dishion, 2005). This third group is of real interest because it directly addresses a comment made by Robins (1966) and frequently cited by trait theorists to the effect that most (about half) antisocial children do not grow up to be antisocial adults. In the OYS study, this group represented 44% of the subset of overt antisocial boys. Moffitt et al.'s (2002) careful analyses of the adult follow-up data for the Dunedin study showed very similar findings. They found that about 8% of their male cohort (10% for OYS) were members of a subset who showed high levels of antisocial involvement during childhood but only low to moderate participation during adolescence. Moffitt and her colleagues labeled them "the recovery group," implying a shift away from the antisocial trajectory. However, from the perspective of the Oregon model, this subset failed to move on and receive advanced training from deviant peers. In the Oregon model, we assumed that these individuals are anything but recovered: They remain antisocial but are limited to overt forms of expression. The fact that they did not participate in activities with their deviant peers suggests either poor peer relationships or active efforts on the part of the child and family to avoid deviant contexts.

Moffitt et al.'s (2002) analyses of this third group found that, as adults, they were suffering from internalizing forms of psychopathology, none had married, many had difficulty in making friends, and many were isolates. According to Moffitt et al., 28% of this third group as adults had court records. This was compared to 8% of the Oregon marginal-isolate group. We hypothesized that this third group would make a substantial contribution in accounting for individuals identified by Robins (1966) as antisocial

children who failed to continue on to become adult criminals. As noted earlier, the 22 members of this third trajectory represented 45% of our sample that had been identified as severely antisocial children.

We suggest that there are three pathways necessary to understand delinquent behavior. Each of them has a very different childhood history. The early-onset delinquent was trained by family members to engage in high rates of overt antisocial behavior and lacks a wide array of social skills. He then moved on to be trained by deviant peers in covert skills. He was arrested before the age of 14 years. The likelihood of adult arrest (from 18 through age 23 years) was .65. The second path began in childhood, with average to low levels of overt antisocial behavior and a relatively marginal level of social skills. As a late-onset group, they become involved with deviant peers in midadolescence. There is the expected increase in covert forms. Most of them desist offending. The third group (marginal-isolate), demonstrate only overt antisocial behavior, predicting juvenile and adult noninvolvement in delinquency.

Loeber and his colleagues (Loeber & Farrington, 2000) have also developed a model that describes three paths to delinquent outcomes. Their overt path is thought to begin in childhood with the advent of minor bullying and aggression. The assumption is that over time, the individual progresses to more extreme behaviors such as fighting and then later strong-arm attacks. The second path, covert antisocial behavior, may also begin in childhood, when it might include relatively minor forms such as lying, truancy, stealing in the home, and vandalism. However, younger performers may also engage in fire setting and shoplifting. In adolescence, the more extreme forms may include substance abuse and health-risking sexual behavior and burglary. The third path, authority conflict, begins with noncompliance and defiance, escalating to running away and truancy. Being on this path increases the risk of also moving along the other paths. The average age for involvement in serious delinquency was found to be 11.9 years. Initiation and maintenance on any or all of the paths are thought to be determined by a combination of 41 risk variables described by Loeber and Farrington.

Whether one takes a simple frequency approach to studying antisocial behavior in children and adolescents or focuses on sequential progressions based on developmental data, it is helpful to consider the ecology within which the behavior emerges and grows. Investigators have found repeatedly that entering in predictors can be useful for improving the understanding of developmental processes and for making critical distinctions in the forms of antisocial

behavior. For example, Poulin and Boivin (2000a) found that proactive aggression was predicted by deviant peer involvement, whereas reactive aggression in middle childhood was not. Moreover, Patterson (1993) found that coercive discipline and associated family management practices accounted for the initial and chronic levels of problem behavior, and peer deviance accounted for growth in problem behavior, mostly in adolescence. An empirical account of antisocial behavior must address the fact that it changes form with development. Furthermore, the mechanisms that produce the changes vary from one form to the other, as do the agents and settings in which the changes occur. In a very real sense, this developmental model shows heterotypic continuity (Cicchetti, 1990). We propose that a functional perspective on social behavior and socialization provides an account of the timing and developmental variation observed in various forms of overt and covert behaviors. For this reason, we review literature about the onset, duration, and course of antisocial behavior as a critical foundation for explanation and, more important, intervention.

THE ECOLOGY

As the science of development and psychopathology matures, one sees clearly the need for integration of various levels of analysis, from biological influences, to microsocial analyses of relationship dynamics, to the study of context, including neighborhoods, schools, and communities. An ecological framework is helpful for organizing these levels of analysis (Bronfenbrenner, 1979, 1989).

The basic tenet of an ecological framework is that adaptation is functional. Our emphasis on social interaction patterns narrows the search to focus on functional dynamics in close relationships that elicit and/or maintain antisocial behavior in children and adolescents. We see the antisocial pattern as functional on at least three time scales. First, the overt antisocial behaviors we described earlier are functional at the microsocial level, in that they effectively control behavior. There seem to be two different mechanisms associated with producing immediate short-term control over the behavior of the other person. The first one identified in our observation studies followed an “escape-conditioning sequence”: During a conflict bout, the child’s persistent or escalating aversive reactions are followed by the other person terminating the bout; for example, the child wins. The other mechanism, and one we frequently encounter in our videotapes of Nor-

wegian families, fits an “avoidance-conditioning model.” If a child’s demands are not met, the child will punish the parents by having a temper tantrum; the parents avoid the temper tantrums by immediately complying with all child demands. Yelling, screaming, profanity, hitting, slander, and psychological assault become tools of microsocial coercive interactions. They are learned implicitly, forming the grammar of family life.

At a longer time scale, but still microsocial, is the role of deviance in forming the glue of friendships. Friendships are unique in the preponderance of positive behaviors. Indeed, when deviance is functional for keeping a relationship together, it remains a primary “shopping” strategy (Patterson, Reid, et al., 1992). Thus, the time scale is both seconds (probably at the very beginning of new friendships) to months and years (Dishion & Owen, 2002). We call this a “deviant friendship process,” or deviancy training for short. The functional time scale may be extended somewhat further as we speculate about the probable function of the deviant peer group in promoting sexual relationships and contexts for early selection of sexual partners (Capaldi & Crosby, 1997; Dishion, Poulin, & Medici Skaggs, 2000; French & Dishion, 2003).

A key assumption of a functional emphasis on social interaction is that thoughts and feelings about relationships may or may not accurately reflect the actual relationship dynamics as revealed through observation analysis (Patterson & Reid, 1984; Patterson, Reid, et al., 1992). Parents referred to clinical settings with a problem child rarely identify their own reaction patterns as part of the problem. Youth are often unaware that their friends are moving them toward behaviors and decisions that will certainly undermine their health and development. Individuals feel their way through the social world, “choosing” responses that avoid or result in punishment. In this sense, consistent with several developmental theorists, relationships define the proximal environment in which change and development transpire (Bronfenbrenner, 1989; Hinde, 1989; Patterson, 1982).

As we shall see, the evidence is compelling that relationship dynamics are part of the problem, but more important, they are critical to the solution in child and adolescent antisocial behavior. Understanding the family and peer relationship dynamics is fundamental to understanding why some interventions intended to reduce antisocial behavior work and others do not (Dishion & Stormshak, in press).

There is a compelling sense, however, in which individuals shape their own futures. An individual can become aware of problematic relationships and dynamics and work to change or avoid those dynamics or reduce their influ-

ence. Individuals clearly shape, manipulate, select, and plan their own futures and avoid pitfalls and take advantage of opportunities to realize goals. This ability to regulate oneself in the social world would seem to increase with age. The ability to do so would be considered a resiliency factor, and the opposite, the inability to resist pressures for deviance and/or addiction, a vulnerability.

Our group has had some difficulty in measuring a construct that reflects individual-level resilience that is not empirically redundant to the antisocial construct. For example, when we formed a multiagent and multimethod construct of competence, we found it correlated $-.85$ with a similarly formed composite measure of antisocial behavior (Patterson, Reid, et al., 1992). We concluded that the global ratings we used to define children's competence and antisocial behavior were simply positive and negative items on a single "good/bad" dimension. Psychometrically, there is a strong tendency for rating individuals, to reduce one's judgments to the least common denominator, which is simply whether the person is liked or disliked (i.e., good or bad; C. E. Osgood, 1962). This fundamental tendency in rater bias is what underlies the validity problem known as monomethod bias (Cook & Campbell, 1979). Another, less technical term for this is what we refer to as the "glop" problem (Bank, Dishion, Skinner, & Patterson, 1990).

The best strategy for avoiding glop is to become more focused and microsocial when measuring a construct (Fiske, 1986, 1987). In the past decade, progress has been made in linking genetic, brain, and behavioral dimensions to define competence as a process of self-regulation (see Rothbart & Posner, Chapter 11, this *Handbook*, Volume 2). In this chapter, we integrate this emerging literature to discuss the possible role of self-regulation in the development of antisocial behavior. Consistent with a social interaction perspective, we assume that self-regulation is highly embedded in relationship dynamics, consisting of a set of behaviors such as turn taking and listening to others. At another level (and temporal scale), it involves following through on tasks, avoiding situations where the temptation to engage in deviant behavior would be too great, controlling how one thinks and feels about things, and planning ahead. These self-regulatory skills are also those often emphasized in effective interventions for reducing antisocial behavior in children (Dishion & Kavanagh, 2003; Dishion & Stormshak, in press; Kazdin, Siegel, & Bass, 1992; Lochman, Barry, & Pardini, 2003; Lochman & Wells, 1996). Self-regulation, therefore, is the most promising candidate for linking individual characteristics to the ecology in a way that will be helpful in understanding the development of antisocial behavior.

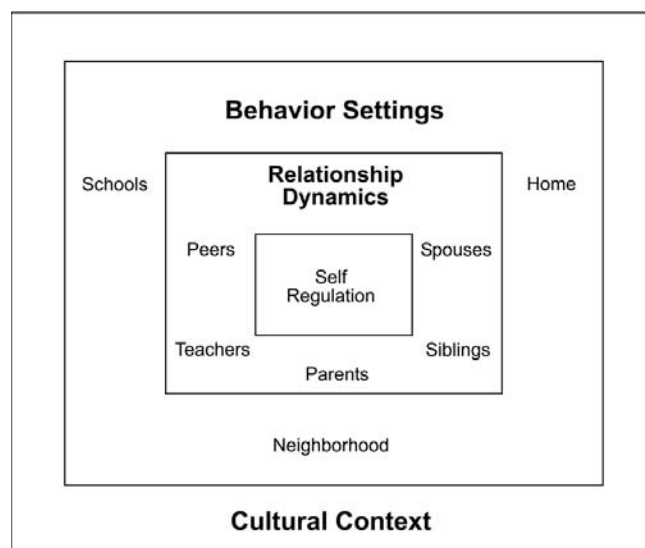

Figure 13.5 The ecology of antisocial behavior.

As shown in Figure 13.5, we invoke three broad domains of constructs to explain the age of onset and severity of antisocial behavior:

1. Relationship dynamics focuses primarily on interactions with parents, siblings, and peers as the proximal training ground for the learning and maintenance of antisocial behavior from childhood through adulthood. Such dynamics are studied by conducting microsocial analyses of interactive dynamics and contingencies, cognition and emotion.
2. Behavior setting stimuli describe the characteristics of contexts to the structuring of relationships that influence problem behavior. Because peer interactions are so important in the development of antisocial behavior, we focus our attention on the public school setting and the formation of peer interactions in children and adolescents.
3. Self-regulation describes the individual's ability to become self-directed with respect to managing daily, weekly, and monthly routines, regulating emotions, keeping in check dysfunctional thinking, and selecting environments conducive to goal-directed behavior.

In addition to these three domains, Figure 13.5 adds the cultural and community context as a conditional variable when considering the viability of an explanatory model. In the past 10 years, a variety of studies have shown variations in dynamics associated with the etiology of antisocial behavior as a function of culture and ethnicity. We address these issues as they pertain to each of the domains reviewed next.

As mentioned, we propose a single model for the development of antisocial behavior that has the potential to be a general application and is relevant to the systematic effort to treat and prevent problem behavior in children and adolescents. We begin with a detailed discussion of relationship dynamics.

Relationship Dynamics

Regardless of theoretical perspective, it is generally agreed that in childhood and adolescent relationships with parents, siblings, peers, and teachers are the basic social ecologies within which antisocial behavior is displayed, practiced, learned, accelerated, or suppressed. During late adolescence and early adulthood, romantic relationships transform into long-term commitments and families; peers become coworkers; authority figures gradually change from teachers to supervisors.

The contribution of parents and peers to the development and course of antisocial behavior can be seen as a layered process that begins in infancy and proceeds through adolescence (see Figure 13.6). From a social interactional perspective (Reid, Patterson, & Snyder, 2002), child socialization is an effortful process that requires adult attention, effort, and skills in managing the minutiae of daily parent-child interaction, as well as the proactive structuring of children's development trajectories. The layers of influence in the socialization process can be seen as hierarchical integration.

The earliest relationship is that of the caregiver and child. Both behaviorists and attachment theorists agree in emphasizing the key role played by the variable *caregiver responsivity* (Patterson & Fisher, 2002). As measured by Martin (1981) and Maccoby (1992) and replicated by Shaw

and Winslow (1997), the variable emphasizes maternal sensitivity and warmth in reacting to infant behavior. What gradually emerges are two general dimensions that describe the parenting domain. One dimension can be characterized as affective in that it emphasizes warmth and relational characteristics. The other dimension can be characterized as contingent/noncontingent; for example, the warm relational parent who is also noncontingent (permissive) is likely to produce an aggressive child, as shown by Baumrind (1971). The coercion model emphasizes the noncontingent parent with only weak relational ties to the child.

Caregiver skills in behavior management (i.e., social and material contingencies) build on the caregiver relationship. Attachment is viewed as a necessary, but not sufficient, precondition for socialization to occur. The child must learn to adapt to the intricate network of implicit and explicit rules that govern behavior and that vary as a function of age and gender.

Figure 13.6 shows that parent relationships influence, and, in turn are altered by, parent-guided socialization. For example, obvious failures to socialize the child are received by the parent as negative feedback and alter several components of the parent-child relationship. A study of the OYS sample showed that school failure was highly correlated with measures of maternal rejection (Patterson, 1986). In turn, both of these areas of activity are bidirectionally related to what transpires in interactions with peers. The sections that follow trace out the details of this interconnected aspect of the socialization process as they unfold over the time course between early childhood and late adolescence.

Parenting Practices

The interest in the relationship between parenting and the development of antisocial behavior cuts across disciplines. In longitudinal studies seeking to predict male adolescent antisocial behavior, parenting practices were among the most powerful predictors (Loeber & Dishion, 1983). Although the general relationship is well established, there is variability from study to study in the magnitude of predictive validity, primarily because of differences in the measurement procedures used to define parenting. Use of parents' recall or reconstruction of their parenting behavior tends to produce lower predictability (Brook, Whiteman, Gordon, & Cohen, 1986; Patterson & Bank, 1986). Children's reports of parenting practices lead to somewhat higher predictive validity (e.g., Nye, 1958; Slocum & Stone, 1965). Outside sources for information about par-

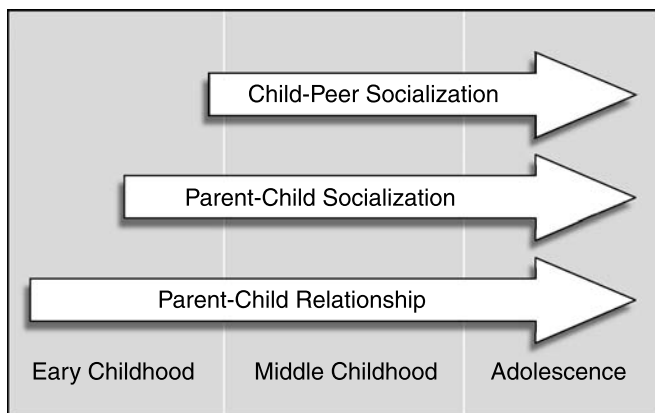

Figure 13.6 Relationship dynamics from early childhood to adolescence.

enting, whether from official records of parent criminality, home visitor ratings, or direct observations, consistently produce the highest level of predictive validity for current and future antisocial behavior.

Patterson's (1982) coercion model focused specifically on the contributions of parent-child interactions to child antisocial behavior. This social interaction model implies an emphasis on parent-child exchanges as the proximal cause of antisocial behavior throughout the life span. Even in this early model, parental cognitions were thought to play a significant role. For example, it was hypothesized that during conflict episodes, both parent negative attributions and anger contributed to the likelihood of escalation. A series of laboratory studies showed that parents of aggressive children tended to be overly inclusive in their definitions of deviant child behavior (Patterson, Reid, et al., 1992). Child behaviors classified by trained observers as within normal range were classified as deviant by parents of problem children. It was assumed that these laboratory measures of parent negative attributions could serve as predictors for disruptions in parental discipline practices.

In keeping with this prediction, Nix et al. (1999) found a low-level path coefficient showing covariation between maternal negative attributions to (teacher- and peer-defined) school aggression constructs. However, as shown in Figure 13.7, the path from parent attributions to school aggression was mediated by parent discipline practices. Snyder, Cramer, Afrank, and Patterson (2005) replicated this mediational model. Social cognitions play a powerful role in disrupting parental discipline practices. However, it is the disciplinary exchanges themselves that function as a di-

rect effects model for overt forms of child aggression. In a later section, we examine findings that show an even more dramatic role for maternal social cognitions in understanding future growth in aggression.

To date, the chief focus of the coercion model has been on the process by which the child learns antisocial behavior within parent-child and sibling-child exchanges. The concept of negative reinforcement is the key to understanding the interaction patterns we see occurring between parents and antisocial children, even in the toddler and preschool years. Such interactions occur at some level in all families from time to time. A high rate of coercive exchanges, however, is hypothesized to train children to use a wide range of coercive behaviors in their effort to shape their social environment.

An important corollary of a coercive parent-child relationship is the concomitant reduction in the adult's attention to the child's development of self-regulation, critical to a variety of prosocial skills (Eisenberg & Fabes, 1998). Again, we do not know which comes first: Does the coercive child behavior cause the shutdown in skill development? Or is it the reduced level of positive parent involvement that sets the stage for the development of coercion? The result is clear and dramatic: It produces long-term outcomes such as failure to acquire homework skills, failure to care for or understand others' thoughts and feelings (empathy), and failure to engage in organized games or group activities. In this fashion, the problem child is doubly handicapped.

Coercion is not only about aggression; it also accounts for general tendencies to avoid and, eventually, conceal and manipulate. The child learns to avoid parent demands through a process of negative reinforcement. Repeated over thousands of trials, the child learns to use coercive behaviors to gain control over a disrupted, chaotic, or unpleasant family environment. In these families, aversive events occur as often as one event every 3 minutes. A conflict bout occurs about once every 16 minutes. Given intensive practice, these coercive patterns become overlearned and automatic. This is contrary to the position taken by Bandura (1989, p. 88) in his influential statement, "Because outcomes effect behavior largely through the mediation of thought, consequences alone often produce little change in behavior." Alternatively, the present writers assume that coercive contingencies operate without conscious, cognitive control. In point of fact, the Nix et al. (1999), Snyder, Cramer, et al. (2005), and Snyder, Schrepferman, et al. (2005) studies show that the impact of cognitions on behavior is mediated by contingencies rather than the other way

Figure 13.7 Maternal hostile attributions in the coercion cycle. Adapted from Nix et. al. 1999.

around. One of the major goals in interventions targeting parenting practices is to help the parent become aware of these automatic patterns and to bring them under more cognitive control (Forgatch & Patterson, 1989).

In the absence of countervailing forces, children may increase the frequency of coercive behaviors, and this, in turn, predicts their moving toward the more severe forms for their age group (e.g., to temper tantrums and physical attacks). As suggested, the coercion process is often not recognized by the participants. Family explanations evolve that suggest that if the child is stubborn (like his or her father?), the marriage is bad, work is interfering, or the school is unfair. We have often found that parent reports about what they are doing yield low predictive validities (Capaldi & Patterson, 1989). The development of observational methodology to record objectively the moment-by-moment interchanges between parents and their children has been critical in evaluating the coercion model. In the OYS, Patterson, Reid, et al. (1992) compared behavior observations and parent interview measures of discipline practices. They found that the correlations between these were low (correlations in the .2 to .3 range), barely satisfying the minimal requirements of convergent validity in construct validation.

The careful longitudinal studies by Shaw and his colleagues (2003) trace out the details for the continuity between toddler and middle childhood status. Toddlers who are low in self-regulation (for their age) and mothers who are depressed are most at risk for engaging in an extended version of the coercion process, accounting for the majority of the children entering elementary school with behavior problems (Shaw et al., 2003). Left on their own, these parents are least likely to improve their parenting practices to the normal range during their child's adolescent. Patterson and colleagues (Patterson & Dishion, 1985; Patterson & Stouthamer-Loeber, 1984) found an association between inept parent discipline practices, parent monitoring, and child antisocial behavior in midadolescence. Thus, cumulative continuity (Caspi, Bem, & Elder, 1989) takes its toll by rendering a very antisocial and violence-prone adolescent (Capaldi & Patterson, 1991; Lykken, 1993).

The issue of whether coercion applies across cultural and ethnic groups is a bit more complex. It certainly is true that parenting practices covary with problem behavior for children across ethnic groups (Catalano et al., 1992; Deater-Deckard & Dodge, 1997; Dishion & Bullock, 2001; Mason, Cauce, Gonzales, & Hiraga, 1996; Steinberg, Dornbusch, & Brown, 1992). There are important differences, however, in the precise form that the coercion process may take across cultural groups. For example, in the recent work by Deater-Deckard and Dodge, reports of

physical spanking were correlated with lower rates of problem behavior among European American children but not with African American youth. We used direct observations to compare high-risk and successful early adolescents in the context of their family (Dishion & Bullock, 2001). When we looked at direct observations of specific parenting practices, such as limit setting and relationship quality, there were anomalies in the findings. For example, relationship quality was quite high in the observations of high-risk African American boys with their parent(s), whereas it was less so for successful African American youth and their parents. Moreover, limit-setting practices were rated as lower for successful African American youth, compared to high-risk African American youth. When using an aggregate family management score based on the 45 minutes of direct observation, we found that the ethnic differences dissolved, and only the differences between high-risk and successful remained. These findings underscore the assertion that to measure parenting well, it is important to consider the pattern of contingencies surrounding the performance of positive, neutral, and negative behavior, and that even global ratings of direct observations are vulnerable to biases and obfuscation (Yasui, Dishion, & Dorham, *in press*). A final point is that interventions that target family management work equally well for all ethnic groups (Connell, Dishion, & Deater-Deckard, *in press*; Dishion, Nelson, & Kavanagh, 2003; Gross et al., 2003; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998).

As children move into adolescence, monitoring becomes an increasingly important aspect of parenting. Patterson and Dishion (1985) found a strong correlation between parent monitoring practices, adolescent delinquent behavior, and deviant peer associations. Inadequate parent monitoring seems to be important in the emergence and maintenance of antisocial behavior in children from middle childhood through adolescence.

Rowe (1994) and Harris (1998) reviewed the findings from twin and adoption studies designed to test for the relative contributions of genes and environments to phenotypic behaviors such as aggression. They concluded that there was no support for the contribution of shared environments to the development of any phenotypic behavior, including children's aggression. They also concluded there was no evidence for the contribution of parenting practices to child aggression. If anything, the evidence indicated that it was the child's behavior that governed parenting practices. There are at least three well-known flaws in the behavior genetics approach that would normally give pause to anyone making such strong claims. The flaws were re-

viewed in detail by Bronfenbrenner and Ceci (1994) and Collins, Everitt, Robbins, Roberts, and Wilkinson (2000). The most salient problems are these:

1. The range is restricted, as shown by Stoolmiller (1998) and by Turkheimer (1991). This is a problem for both adoption and twin designs. Both strategies employ truncated environments, and as a result, the chances of finding environmental effects are severely curtailed.
2. It is the twin design studies that fail to find any effects for shared environments or for parenting practices. There are now three major studies that show that identical twins share an environment that significantly increases their similarity (Carey, 1992; Rose & Kaprio, 1987; Tambs, Harris, & Magnus, 1995). This means that the heritability equation 2 (monozygotic-dizygotic) is confounded.
3. The estimate of heritability varies widely as a function of method of measurement. After reviewing 24 studies, Miles and Carey (1997) concluded that the most salient finding was that estimates of heritability varied as a function of method of measurement. Estimates based on parent ratings tended to show high values for heritability, whereas those based on observation data were very low. These conclusions were supported by two more recent studies by Leve, Winebarger, Fagot, Reid, and Goldsmith (1998) and Deater-Deckard (2000).

In reacting to the Rowe-Harris claims, developmental psychologists such as Collins et al. (2000) took the position that the strongest test of the parenting practices model would be an experiment in which families were randomly assigned to experimental and comparison groups. The experimental group would receive parent management training and the comparison group would not. The design would require data showing significant improvements in parenting skills for families in the experimental group, but not in the comparison group. Furthermore, the data must show improvements in child outcomes for the experimental group but not for the comparison group. Finally, the magnitude of change in parenting must covary with the magnitude of change in child outcomes.

The study by Dishion and Kavanagh (2003) was one of the first to fulfill the demands for an effective experiment. They randomly assigned parents of 150 problematic early adolescents (males and females) to the Adolescent Transitions Program (ATP) or to a nontreatment control group. ATP consisted of three versions of intervention: parent-focused training, teen-focused training, and a joint focus on parent and teen. Involvement in ATP was associated with

reductions in parent-child observed negative engagement, which, in turn, were reliability correlated with reductions in teacher ratings of antisocial behavior in school. More recently, Dishion, Bullock, and Granic (2002) found that random assignment to family-centered interventions reduced deviant peer involvement and adolescent substance use (Dishion, Kavanagh, Schneiger, Nelson, & Kaufman, 2002). An analysis of direct observation of parent monitoring practices revealed that changes in parent monitoring were associated with changes in deviant peer involvement and substance use.

The most careful mediation analyses to date are those conducted and reported by Forgatch and colleagues studying children undergoing divorce. The researchers documented that random assignment to parenting interventions showed significant increases in effective discipline and monitoring and in measures of positive parenting, and produced parent-child coercion, which, in turn, was associated with reductions in child antisocial behavior (Martinez & Forgatch, 2001). These changes were associated further with significant improvements in child antisocial behavior, delinquency, and school achievement (Forgatch & DeGarmo, 1999, 2002). It is important to note that the evaluation of these intervention studies carefully selected independent and objective indices of behavior (not parents' report) to minimize the Hawthorn effect on global ratings of functioning.

Attachment and Positive Parenting

As noted earlier, there are impressive areas of agreement between attachment and coercion theories (Patterson & Fisher, 2002). Both theories agree on the fundamental importance of parental responsiveness as being a necessary condition for socialization. Both theories define parental responsiveness as the contingent actions of the parent in reacting to the child. Both the attachment theorists (Van den Boom, 1994) and the behavioral approaches (Martin, 1981; Shaw & Winslow, 1997) predict the association between noncontingent parenting and infant distress. Both would see the impact of contextual factors, such as maternal depression, leading to negative child outcomes as mediated by disruptions in parental responsiveness.

As pointed out in Patterson and Fisher (2002), the two theories differ dramatically in their explanations of the means by which parental responsiveness produces child outcomes. In the behavioral view, the contingent reactions shape both the child outcomes and parent behavior. Some of the literature relevant to this assumption is reviewed in a later section. Attachment theorists (Ainsworth, 1989;

Ainsworth & Bowlby, 1991; Rutter, 1995) take the position that the impact of parental responsiveness on child outcome is entirely mediated by mechanisms such as infant level of attachment, the child's internalization of parental values and standards, and the child's attributions. The brief review by Fagot and Kavanagh (1991) suggested only limited predictability from attachment classification to child adjustment for males but not for females and for at-risk families, rather than for normal families. It can be said that in terms of variance accounted for, attachment theory makes only a limited contribution.

Although both theories agree in their emphasis on the importance of parental positivity on child outcomes, the empirical findings testing these assumptions pose an interesting problem for both theories. When we constructed multi-method, multiagent indicators for a range of child deviant and prosocial behaviors, our correlational models showed a very interesting pattern of findings (Patterson, Reid, et al., 1992, see Table 5.7). As expected, when examining antisocial outcomes, the measures of disrupted parenting (monitor and discipline) accounted, on average, for about 16% of the variance, and measures of positive parenting accounted, on average, for about 3%. We had expected that models built to account for prosocial outcomes such as achievement, self-esteem, and peer relationships would show the reverse pattern. Our best attempts to specify parent involvement, parent support, and dyadic problem solving produced significant correlations with child achievement, but on average, they accounted for only about 3% of the variance. The results were disappointing and lead us to believe that perhaps we did not focus enough on specifying the measurement models for positive parenting.

We were surprised to find that the measures of disrupted monitoring and discipline seemed to predict both negative and prosocial outcomes. They accounted for about 3 times as much variance as did measures of positive parenting! The findings suggest the interesting possibility that when the coercion process is well under way, one of the most important concomitants is a shutdown of all prosocial support mechanisms. If the family is extremely coercive, it is known that there is little reinforcement or support for prosocial activities. The amount of support for prosocial behavior is entirely a function of the level of pathology. If this is true, then an experiment should show that reducing coercion levels would be accompanied but a sudden increase in the relative contribution of parent support, parent involvement, and problem solving.

Some recent findings from prevention studies are of particular interest because they seem to support such an idea.

The data from a randomized prevention trial showed that growth in parent positivity (support, involvement, problem solving) played a dominant role in bringing about change in child compliance behaviors (Martinez & Forgatch, 2001). The path coefficient from growth in positive parenting to changes in child compliance was $-.54$. The comparable path for improvements in discipline and growth in compliance was also significant, but a much lower $.19$. A single study is hardly creditable, but the findings set the question in proper perspective. What does positive parenting contribute to the process of change?

F. E. M. Gardner (1989) made significant progress on this scientific issue. She asserts that it is necessary not only to look at the immediate reaction of compliance or noncompliance, but also to consider the outcome of the conflict minutes afterward. Using this approach, she found that mothers of conduct problem children were 8 times more likely to relinquish demands than mothers of normal children. Also, mothers of nonproblem children handled 43% of the conflict episodes inconsistently, compared with 5% of mothers of normal children.

Another criticism by F. E. M. Gardner (in press) of the coercion model is that it is too clinically oriented and does not fully consider the causal impact of positive features of the family environment. In coercion theory, it is the use of aversive exchanges, rather than positive exchanges that disrupts child development. In her observation, the more entrenched the parents become in the coercion process, the further they shrink from relationship skills that they would enjoy under more favorable circumstances.

F. E. M. Gardner (in press) went on to isolate deficits in positive interactions that characterize families with antisocial children. She found that proactive parenting, in particular, differentiated parent-child interactions of conduct problem and normal children. This parenting skill involves a combination of structuring situations to avoid misbehavior, engaging the child in positive, joint activities, and using verbal prompts that elicit positive behavior in children. Although these positive practices may be disrupted because of the coercion process, the lack of proactive parenting may have a unique effect on multiple aspects of child social development not predicted by coercive interactions.

Patterson (1986) tested a structural equation model that demonstrated a strong correlation between harsh, abrasive, and inconsistent parent discipline and child antisocial behavior. This model was replicated across the two cohorts of the OYS with a single-parent sample and a clinical sample (Forgatch, 1991). The longitudinal studies by Shaw and colleagues (1998) demonstrated that these processes are in

place at a very early age. Their models combine both a contingency and an attachment view and use it to account for the emergence of behavior problems in early childhood. To measure the attachment relationship, however, they did not use the Strange Situation task, but innovated a process measure. They employed an innovative highchair task pioneered by Martin (1981) to measure parents' responsiveness to the child. Shaw and colleagues found that the lack of parent responsiveness in infancy combined to account for variation in antisocial behavior.

These variables interact to account for the very early emergence of behavior problems (Shaw, Keenan, & Vondra, 1994). The study showed that child noncompliance and mother's nonresponsiveness combined to predict overall levels of aggression by age 24 months. Moreover, at 24 months, an aggression-by-maternal-nonresponsiveness interaction term predicted overall levels of aggression by age 36 months. As the longitudinal study proceeded, rejecting parenting was added to the prediction equation. Rejecting parenting at 24 months predicted the highest rates of aggressive behavior by age 4 (Shaw et al., 1998). Levels of marital conflict were also highly correlated with rejecting parenting (Shaw, Winslow, & Flanagan, 1999), which combined to account for behavior problems by age 5. Ingoldsby, Shaw, and Garcia (2001) followed the sample into school, finding that the pervasiveness of family conflict predicted aggression with peers at school. Most recently, using a trajectory analysis approach to analyze their longitudinal data, Shaw and colleagues (2003) found that children with low levels of self-regulation (in this case, inhibitory control), who also had depressed mothers, were most likely to be aggressive as toddlers and to continue on the antisocial trajectory to the second grade of elementary school.

Most investigators working in this area feel that the parenting model can be strengthened. For example, F. E. M. Gardner's work suggests the importance of identifying proactive parenting skills, and Shaw's work reveals the unique role of parents' responsiveness in toddlerhood to socialization.

The groundbreaking studies by Nix et al. (1999) and Snyder, Cramer, et al. (2005) dramatically expand the model by integrating parenting variables with measures of parental attribution. In this area, there are also studies by Stoolmiller and Snyder (2004) that stitch together models for emotion with models for parenting. There is one more dimension to this struggle that should be noted: A study by Forgatch, Patterson, and Ray (1996) showed that the parenting models that adequately described individual differences in aggression did not fit when applied to growth data

for aggression. Patterson (1993) also found that the model that explained intercept values for antisocial behavior did not fit in models for growth in antisocial behavior. Different models were also required for intercept and growth models of delinquency.

It seems, then, that we may require one parenting model to explain individual differences in aggression but a quite different one for modeling growth in antisocial behavior. In keeping with this distinction, Snyder, Cramer, et al. (2005) found that discipline practices did not contribute to measures of growth assessed at home or school. However, a product term (discipline) by mother (negative attribution) was a significant predictor for growth in both settings.

In summary, there is little doubt that parenting practices are highly correlated with child antisocial behavior. It is also the case that improvements in parenting practices during well-designed intervention studies produce decreases in a child's antisocial behavior. The strength of these findings and the fact that they are replicated means that we can now set about the task of improving the models.

Siblings

It has been said that siblings are no more alike than two people chosen at random (Plomin & Daniels, 1987). It turns out that method variance again distorts our view of the contribution of siblings (Hoffman, 1991); that is, the lack of similarity among siblings ($r = .16$) found across samples may be an artifact of data based on personality inventories. Research employing alternative assessment methods, including direct observation, paints a different picture of similarity between siblings on several indices of adaptation in the home and school settings in the middle childhood years. It turns out that when effective measures are employed across siblings, there is a robust correlation for aggression.

Studies that attempt to disentangle the influence of different family agents on the socialization of the child and the development of antisocial behavior are just beginning. Considerable evidence suggests that the influence of siblings is significant. One recalls the finding, first reported by West and Farrington (1973), that 5% of the families accounted for 50% of the crimes in an urban London sample. This finding implied that siblings share a common trait for antisocial behavior. We suspect that siblings are fellow travelers on the path to antisocial behavior (Patterson, 1986).

Clinical experience tells us that children referred for conduct problems often differ little from their nonreferred siblings. In their home, siblings' rates of aversive behavior

frequently are comparable to that of the target child. Patterson (1986) reported a correlation of .61 among brothers referred for conduct problems who were observed in the home. Patterson, Dishion, and Bank (1984) found a correlation of .43 among boys and their siblings as observed in the home. Patterson (1984) proposed that siblings, as well as other family members, shared a mutual trait toward aggressiveness. The thought is that the coercion process, as previously discussed, is elicited by inept parenting practices (Patterson, 1982; Patterson, Reid, et al., 1992) and has an impact on all members of a family system.

Strong support for the parenting hypothesis was provided in an intervention study reported by Arnold, Levine, and Patterson (1975). In a reanalysis of clinical cases seen for child aggressive behavior, they found that all siblings decreased observed aversive behavior following parent training, even though only the problem child was targeted for treatment. However, the high correlations between siblings on observed aggressive behavior are confounded because siblings are most often interacting with each other when observed in the home. The finding also needs to be replicated with a randomly assigned experimental control group.

There is some evidence for sibling similarity outside the home. For example, the work of Lewin, Hops, Davis, and Dishion (1993) showed convergence among siblings on such measures as negative peer nominations ($r = .65$), teacher ratings on aggression ($r = .48$), and observed positive peer behavior in the classroom ($r = .47$). The correlation among siblings in teachers' reactions to each child in separate classrooms was surprising. Behavior observations in the classroom revealed a correlation of .72 ($p < .001$) in observed teacher disapproval. Note that these were independent observations of each of the siblings in separate classrooms with different teachers.

A simple generalization model cannot account for siblings' similarity in the school setting. Although siblings' behavior in school is intercorrelated, as is siblings' behavior in the home, two studies showed that there is not a high correlation between children's aversive exchanges with their siblings and their peer acceptance of antisocial behavior in school (Abramovitch, Carter, Pepler, & Stanhope, 1986; Dishion, 1987). Bank and Burraston (2001) also showed that sibling conflicts in the home were a poor predictor for deviant peer contacts in the school.

Aside from the contribution of siblings to the coercion process, there is recent evidence that siblings may function to facilitate antisocial behavior by two mechanisms: first, by reinforcing deviant talk and behavior in families, and second, by forming coalitions that undermine parents' ability to socialize young adolescents. The process has

been referred to as *sibling collusion* (Bullock & Dishion, 2002). In this study, observers coded videotapes of family interactions of high-risk and normative young adolescents for sibling collusion. We found that sibling collusion was highly correlated with young adolescent problem behavior, as defined by teachers and self-reported, and that this effect held when controlling for involvement with deviant peers. Incidentally, sibling collusion was also highly correlated with the young adolescents' involvement with deviant peers, suggesting yet a third function of siblings, in that older siblings may in fact provide a bridge to the deviant peer group.

In a second study, Stormshak, Comeau, and Shepard (2004) examined the role of sibling "deviancy training" as measured by direct observations without the parents present. Using latent growth modeling, they found that direct observations of sibling deviancy training and their own problem behavior were strongly associated with growth in adolescent problem behavior, even when controlling for the behavior of peers. Of course, in many ways, the contribution of siblings is difficult to study in isolation from peers, as sibling relationships are often embedded within peer networks, especially in adolescence.

More recently, Bullock, Bank, and Burraston (2002) examined the prognostic value of sibling conflict to adult continuance in antisocial behavior. These investigators examined collected expressed emotion indices of sibling negative affectivity and conflict. Compared to earlier measures of home observations of sibling conflict, coded expressed emotion from 5 minutes of audiotaped speech samples predicted long-term patterns in antisocial behavior over and above direct observations of coercive sibling interactions. These data point to the potential importance of the expressed emotion methodology for studying relationship processes and indicate the potential long-term and unique influence of siblings to antisocial behavior.

Peers

It has become increasingly clear that most covert forms of antisocial behavior (proactive aggression, relational aggression, stealing, etc.) are embedded within peer and friendship relationships. In contrast to our previous review, we posit peers as a major proximal cause of antisocial behavior, beginning in early childhood and accelerating in influence during early adolescence.

We see this as being accomplished in three major ways: (1) Antisocial behavior interferes with positive peer relations, depriving children of the positive benefits of peer learning and confining them within the social niches of

marginal adjustment; (2) children may act as models and a source of reinforcement for antisocial behavior; and (3) as children develop friendship networks, support for antisocial behavior is established by providing both reinforcement and opportunity for such behavior. We address each of these issues in turn.

Entry to school may be the first occasion during which the child is exposed to significant numbers of nonrelated age mates (French, 1987) and, as such, provides the conditions for establishing the peer culture. Patterson et al. (1967) have shown that one of the consequences of exposure to other children is an increase in aggression. Their microanalysis of preschool children's interactions revealed that peers provide very rich schedules of positive reinforcement for coercive behavior, with 80% of coercive behavior producing successful outcomes. Instigators and victims are not random: Certain children provide reinforcement for aggression, with the consequence being an increase in the victimization of these children (Olweus, 1979). Snyder, West, Stockemer, Givens, and Almquist-Parks (1996) found that, in Head Start preschools, peer choice and reinforcement were salient predictors of early aggression. Affiliative structures and coalitions seem fundamental to the human condition even in early childhood and are germane to the development of antisocial behavior (Strayer & Santos, 1996). A recent study by Snyder, Schrepferman, et al. (2005), and colleagues revealed that as early as the 1st year of elementary school, peer interactions (i.e., deviancy training; see later discussion) could be identified among children and their classmates that predict escalations in antisocial behavior during the 1st and 2nd years of school. Kellam, Ling, Merisca, Brown, and Ialongo (1998) also find that the level of aggression in children's 1st-year classroom predicts long-term patterns of problem behavior. These reinforced patterns of aggression are common and continue into at least early adolescence. We see the early school maladaptation leading to marginal school adjustment, which amplifies deviant peer affiliation networks, which, in turn, provide a proximal context for the refinement and growth in new forms of problem behavior.

The impact of peers on antisocial behavior is also seen in the work of Dodge, Price, Coie, and Christopoulos (1990). Using data from a series of playgroup sessions involving previously unacquainted peers, they found that 50% of the aggression observed in these play sessions was accounted for by a mere 20% of the dyads. As might be expected, these dyads consisted primarily of members identified by their aggressiveness. This research is complemented by a paper presented by Cillessen (1989), in which

it was found that triads of low-status first-grade children were the most highly aggressive; mixed dyads (low and high status) produced considerably lower levels of aggressive behaviors. Thus, the antisocial traits of individuals merge to create a dyadic tendency to engage in antisocial behavior. When both members are antisocial, an amplification of maladaptive characteristics is likely. These data also raise the issue of deviant peer influences as early as middle childhood.

Much of the research on the role of peers in middle childhood antisocial behavior focuses on children's acceptance within the peer group, or sociometric status. Antisocial behavior has emerged as the most consistent correlate of social rejection in children (e.g., Coie & Dodge, 1988; French & Waas, 1987). Aggression is not, however, consistently associated with peer disapproval. Fighting back from a provoked attack may be positively associated with social status (Olweus, 1979), whereas unprovoked attacks seem to be a pathogenic sign of a general antisocial trait. Furthermore, antisocial behavior appears to account for only about 50% of peer rejection in boys (French, 1988) and somewhat less in girls (French, 1990).

The clearest evidence of the impact of aggression comes from observations of playgroups comprising previously unacquainted members. Coie and Kupersmidt (1983) formed playgroups consisting of four boys who differed in status. Rejected boys exhibited more physical and verbal aggression than other group members. Similar findings were obtained by Dodge (1983) in a study of unacquainted groups comprising eight boys unselected by status. Boys who eventually were rejected by their companions exhibited more physical aggression, inappropriate play, and hostile verbalization than other group members. In comparing the role of overt aggression and relational aggression to peer rejection, Crick (1996) found that overt aggression was most correlated with peer dislike.

It is not always true that antisocial behavior is associated with peer dislike. Stormshak et al. (1999) examined the covariation across classrooms between peer social preference and behavior problems. Apparently, some classrooms are settings for peer contagion, as in these, behavior problems lead to positive peer relationships.

The child's movement out of middle childhood into adolescence is marked by increased involvement with peers and affiliations with larger social groups. Much of the research on the contribution of peers to the development of antisocial behavior has focused on the impact of social groups. These are larger than friendship dyads and can be categorized as cliques or crowds (Brown, 1989). Cliques generally consist of fewer than 10 members who frequently

interact with each other. In contrast, crowds are defined on the basis of reputation, and members may or may not interact with each other.

There is evidence that children who are rejected by their peers (a significant percentage of whom exhibit antisocial behavior) begin to associate together during the elementary school years. These children are more likely to interact with younger peers, other rejected children, and individuals with whom they are not friends (Ladd, 1983). These groups become increasingly solidified during early adolescence. Contributing to the formation of these groups is the adolescent quest for autonomy and vulnerability to peer pressure (Steinberg & Silverberg, 1986). An additional factor is the normative transition from the small elementary school environment to the larger, more impersonal middle and high school settings, where there are large numbers of age mates with whom to associate and considerable freedom from adult scrutiny.

Dishion, Patterson, Stoolmiller, and Skinner (1991) found that low parent monitoring, poor academic skills, and peer rejection in middle childhood accounted for associations with deviant peers by early adolescence, even after controlling for prior levels of antisocial behavior. Although the deviant peer construct was stronger at a later age, there was indication that deviant peers were identifiable in the elementary school setting, as reported by children, teachers, and parents (Dishion, 1990). There was respectable stability in involvement with antisocial peers from ages 9 to 10 and 11 to 12, reflected in a standardized beta of .26 ($p < .01$) when controlling for family, school, and the child's behavior at age 9 to 10. Cairns, Cairns, Neckerman, Gest, and Garipey (1988) found that aggressive children in middle school tended to associate more as a function of mutual attraction than of peer rejection. In addition, Cairns, Cadwallader, and Neckerman (1997) reviewed literature suggesting that adolescent members of gangs are a cast of the formerly ostracized and alienated. We recently established that peer rejection in the 1st year of middle school was a unique predictor of gang affiliation by the end of middle school, controlling for earlier measures of antisocial behavior (Dishion, Nelson, & Yasui, in press). One interpretation of peer aggregation is that children actively select environments that fit their genotype, and that these environments serve as nonshared environmental influences on child and adolescent problem behavior (Harris, 1995; Rowe, Woulbroun, & Gulley, 1994).

A study by Bullock, Deater-Deckard, and Leve (in press) was one of the few behavior genetic studies on deviant peer affiliation conducted using a multiagent and multimethod assessment. This study used a twin study

(Leve et al., 1998) to determine heritability of deviant peer affiliation. Multiple ratings of deviant peer affiliation were obtained for monozygotic and dizygotic twins, including direct observations of friendship interactions and two independent teacher ratings (teachers rated siblings and peers independently). The portion of variance attributable to genotype and shared and nonshared environments varied dramatically by assessment method (one measure of teacher ratings yielding the highest heritability). Consistent with previous analyses of this sample, direct observations produce zero heritability coefficients and high shared environmental coefficients. The studies from this sample are critical for our understanding of the methodological barriers to disentangling, unambiguously, nature from nurture on many indices of social development, including deviant peer affiliation.

Association with deviant peers is the strongest predictor of escalating adolescent problem behavior. The large-scale, longitudinal study using a national probability sample reported by Elliott et al. (1985) focused on the role of deviant peers in the etiology of adolescent delinquent behavior. They found that self-reported involvement in a deviant peer group accounted for substantial variance in subsequent levels of self-reported delinquency in middle and late adolescence, even after accounting for previous levels of delinquency. This held for males and females and generalized from minor delinquency to more serious index offenses and serious substance use.

Even more compelling is the work by Thornberry and Krohn (1997) on the influence of gangs on problem behavior. One would think that gangs were simply another form of deviant peer group influence. The important work of Thornberry and Krohn shows that gangs actually contribute to increases in delinquency, after controlling for deviant peer affiliation. Although deviant peer behavior and gang membership are highly correlated, the latter provides independent prediction of problem behavior. This suggests that formation of strong group ties with a verbal label amplifies the influence of deviant peers on behavior. This emerging area of research is very important and, we hope, will lead to further clarity about the possible mechanisms. Kiesner and colleagues (Kiesner, Dishion, & Poulin, 2001) found that identification with a deviant peer group increased the level of influence on future behavior. We discuss later in the chapter the complementary hypothesis that the social interactions within a gang, replete with mutual identification, account for the influence of gangs on problem behavior.

Not only do adolescents who engage in antisocial behavior tend to associate with other antisocial adolescents, but these groups often commit criminal acts. Aultman (1980) carefully reviewed juvenile records in Maryland and found

that 63% of all recorded offenses were committed in the company of two or three peers. Group involvement tended to vary with the type of offense, with 68% of property offenses and 43% of violent offenses committed by groups. Girls were also likely to commit offenses in the company of others, with 57% of their offenses committed in groups. In an analysis of self-reported delinquent acts, Gold (1970) estimated that 75% of all delinquent acts were committed in the company of friends.

The correlations between deviant peer involvement and antisocial behavior were quite high ($r = .40$ to $.59$) and held when both constructs were measured using multiple methods of measurement for both constructs (Patterson & Dishion, 1985). The relation held when the antisocial trait scores were correlated, based on independent reports, for two boys who were friends. For example, Dishion, Andrews, and Crosby (1995) found a correlation of $.42$ ($n = 181$) between the OYS boy's antisocial behavior and that of his best friend. The correlation between the boy's substance use was even higher ($r = .52$; Dishion et al., 1995), supportive of the finding reported by Kandel (1986) that attitudes toward substance use tend to be a salient sorter of friendship cliques in early adolescence.

To study the friendship interactions associated with antisocial behavior, OYS boys 13 to 14 years old were asked to bring in their closest friend to complete a 25-minute videotaped problem-solving discussion. Dishion, Andrews, and Crosby (1995) found a tendency for the friendships of antisocial boys to be abrasive, less stable, and less satisfying to the boys themselves. As would be expected from coercion theory, the antisocial boys tended to be bossy with their friends, were involved in negative reciprocal cycles, and developed relationships that tended to end in disharmony within a year.

Since our last writing, we have conducted several studies identifying the mutual influence processes in adolescent friendships that are associated with escalations in substance use (Dishion, Capaldi, Spracklen, & Li, 1995), self-reported delinquency (Dishion et al., 1996), and adolescent violence (Dishion, Eddy, Haas, Li, & Spracklen, 1997). When the videotapes were recoded using a system that captures a process we refer to as deviancy training, the predictive validity of those friendship interactions increased considerably. The process involves a statistically reliable contingency between deviant talk and laughter, analyzed at the level of the dyad. In each of the studies that follow, 25 to 30 minutes of videotape coded for deviancy training was associated with increases in problem behavior, controlling for past behavior. The findings were extended to understanding problem behavior in adolescent girls (Dishion, 2000). Patterson et al. (2000) found that de-

viant friendship process predicted multiple forms of adult antisocial behavior (arrests, unsafe sexual practices, and substance abuse), controlling for deviant peer association.

As one might suspect, the causal linkage between deviancy training and problem behavior is bidirectional. Dishion and Owen (2002) followed the OYS boys from age 10 through age 24. They found that, as hypothesized, deviant friendship process at age 14 predicted multiple forms of substance use at age 16 years. However, substance use at age 16 invariably predicted selecting deviant friendship process at age 18. Thus, substance use reduced the stability of deviancy training from ages 14 to 18 ($r = .53$, for a 30-minute sample of behavior). We concluded that substance use could also serve as a process for connecting youth to friendship networks and cliques that encourage deviancy training.

Several models have been applied to the direct observation data that assess deviancy training in adolescent friendships. The most exciting to date is the application of a dynamic systems framework to understanding peer influence. In a study conducted by Granic and Dishion (2003), we found that the tendency for some adolescents to engage in deviant talk could be conceptualized as an attractor. In this analysis, it was found that some dyads' deviant talk episodes tended to get longer in duration over the course of the 30-minute observation session. The slope score describing this growth in duration was actually predictive of future adolescent problem behavior, controlling for prior behavior.

One of the advantages of a dynamic systems framework is the use of state-space grids to capture the entire social interaction matrix of a relationship (Lewis, 2000). As shown in Figure 13.8, a state-space grid provides a visual inspection tool for identifying multiple dimensions of relationship dynamics, including attractors, phase transitions, flexibility, rigidity, and the like. We have applied information theory, in general, and the entropy index, in particular, to describe the level of organization in a sequential relationship interaction (Krippendorff, 1986). Low entropy suggests a highly organized interaction process, in that two individuals are moving together in synchrony. High entropy reflects a state of complexity and randomness. In classic thermodynamics, high levels of organization in movement require more energy than randomness. Thus, in general, if relationships are like matter in the universe, there is a tendency toward randomness without effort and attention from the interacting partners. As can be seen in Figure 13.8, both antisocial and normal dyads have low and high entropy scores. In fact, level of entropy was uncorrelated with concurrent problem behavior (Dishion, Nelson, Winter, & Bullock, 2004).

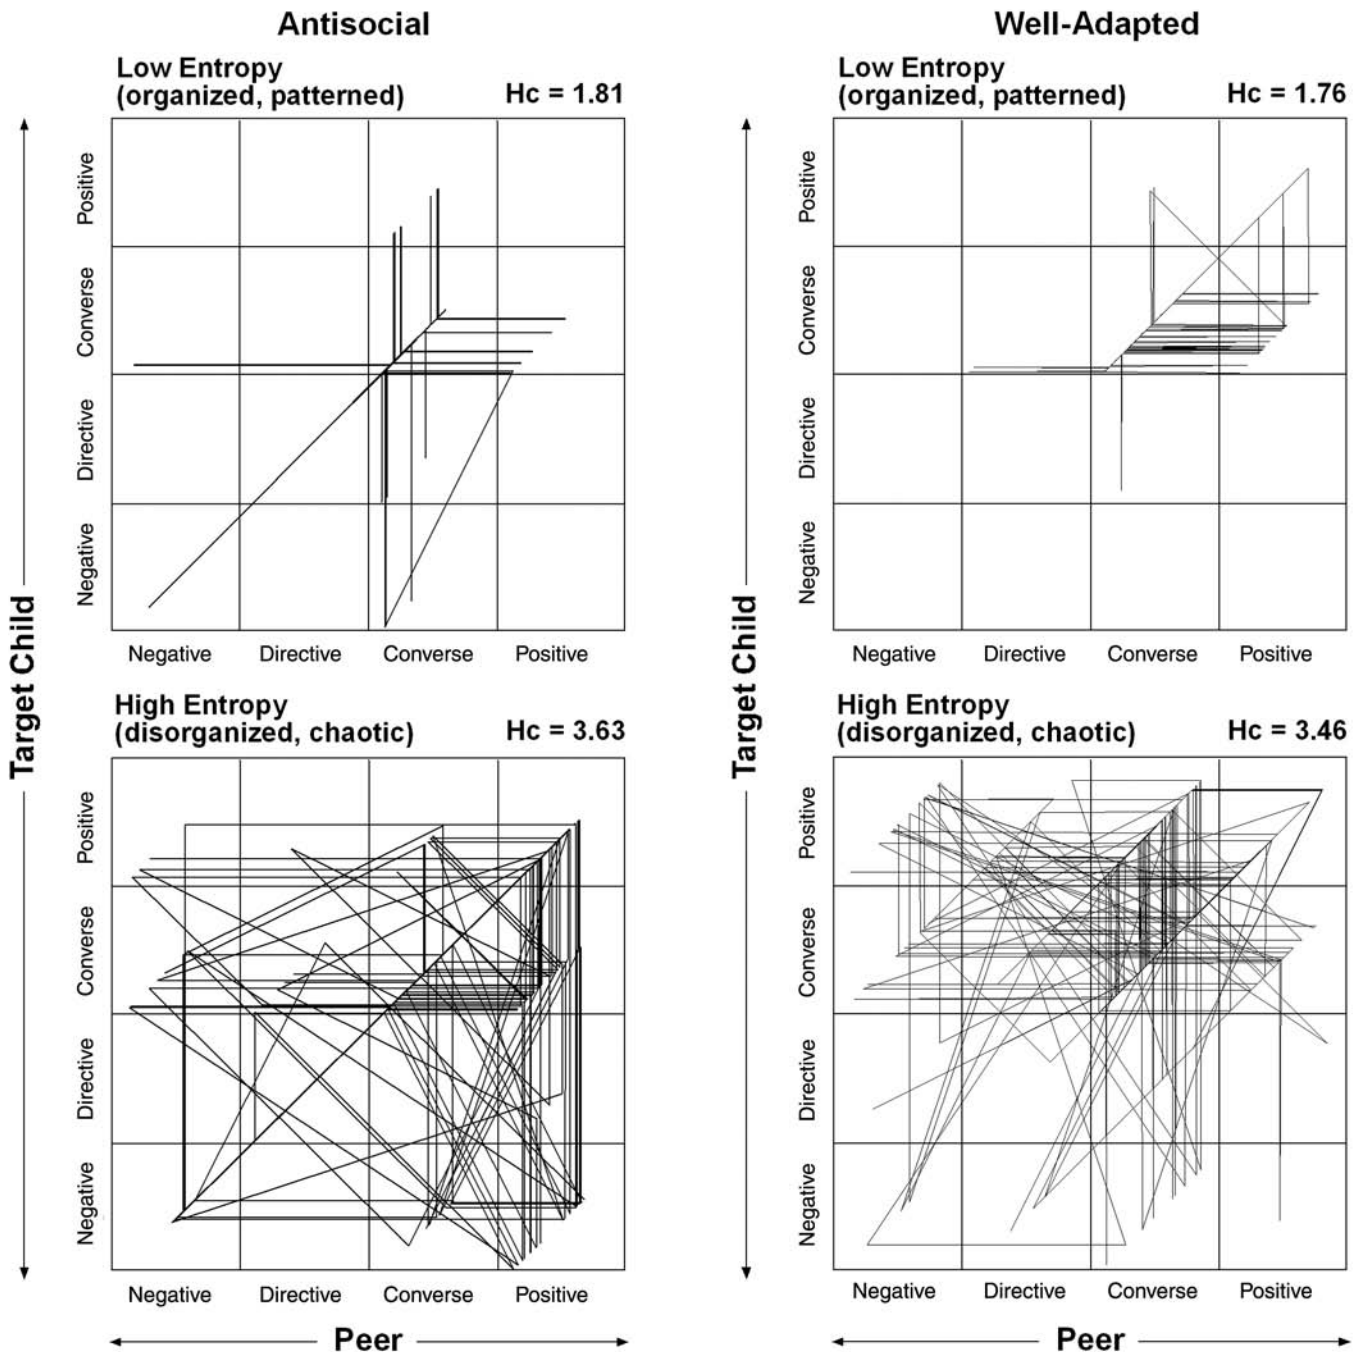

Figure 13.8 Peer process state space grids. Adapted from Dishion, Nelson, et al., 2004.

When following the OYS boys to age 26 and predicting their adult substance use and antisocial behavior, we found that boys with high levels of deviancy training and low entropy scores at age 14 were the most likely to engage in these multiple forms of problem behavior in adulthood. The interaction between the deviancy training and entropy scores was so dramatic that it appeared that the adolescents who organize their relationships around deviance are the

most at risk for long-term adjustment process. This is an important finding as it suggests that deviance is an active, constructive process for some individuals, not just a form of arrested socialization.

We recently took the entropy analysis one step further. As mentioned previously, we have had some trouble in trying to measure a construct of competence and social skill that was empirically nonredundant to antisocial behavior.

Dishion and Pihler (2005) recently observed a group of friendship interactions of three groups of adolescents: early-starting persistent, late-starting, and successful youth. In addition to coding deviancy training, as defined earlier, a measure of dyadic mutuality was used as a macro rating of each interaction episode. Mutuality was defined as listening, turn taking, lack of self-centeredness, empathy, and shared understanding. As suspected, as a group, early-starting persistent youth were generally lower on mutuality and highest on deviant talk compared to late-starting and successful youth. Moreover, females were much higher on mutuality than males. What is interesting, however, is that there was an interaction between friendship mutuality and the youths' deviance in predicting problem behavior. Like the entropy finding, youth who were both more mutual and deviant were the most likely to be arrested.

Dyadic mutuality is assumed to be a partial reflection of the youth's ability to self-regulate, with respect to selecting friends with similar values and being able to be skillful in relationship interactions. However, as we see, if a youngster is deviant, this trait may not bode well for his or her long-term outcomes. The measurement of regulation is quite complex and requires adding specific responses to social interactions at its core.

Sophistication in measurement, analytic models, or longitudinal data does not ignore experimentation in establishing causal influence (Cook & Campbell, 1979). One would think that if peers are powerful in their influence on problem behavior, they could potentially be used therapeutically in promoting self-regulation or prosocial behavior. It is interesting, in fact, that despite the widespread aggregation of high-risk youth into programs, interventions, and settings for delivery of therapeutic, educational, and remedial interventions, there are very few studies that show these programs are effective.

In fact, we found that aggregating high-risk young adolescents into cognitive-behavioral interventions to promote prosocial self-regulation actually increased problem behavior. In a randomized trial involving assignment to parent and peer interventions, we found that youth assigned to peer interventions show short-term (Dishion & Andrews, 1995) and long-term increases in self-reported smoking and teacher ratings of problem behavior (Poulin, Dishion, & Burraston, 2001). Negative effects for peer aggregation were indeed attributable to informal interactions among youth in the groups (before and after the session) that were coded as deviancy training (Poulin, Dishion, & Burraston, 2001). Had our study been the only one that documented iatrogenic effects for peer aggregation, we might have accepted these data as anomalous. However, in collaboration

with our colleague, Joan McCord, we also found that the 30-year iatrogenic effects of the Cambridge Somerville Youth Study were, indeed, attributable to the young adolescent boys being sent to summer camps. The odds were 10 to 1 that if a high-risk boy was sent to a summer camp on two consecutive occasions, he was likely to have a 30-year negative outcome compared to his randomly assigned control (Dishion, McCord, & Poulin, 1999).

A repeating theme in this chapter, and in developmental psychopathology in general, is the synergistic relationship between intervention research and developmental research. The random assignment studies showing negative peer effects suggest that peer dynamics are indeed powerfully causal (at least bidirectional causation) with respect to problem behavior in early adolescence. There is a need for a broader ecological view on peer influence, one that incorporates parent and peer influence simultaneously.

Parent-Peer Mesosystem

The challenge to developmental theorists and researchers is to think systemically about the joint influence of multiple relationship contexts on social behavior. Most of the work in this area has considered the joint influence of parents and peers. It is often said that parental influences diminish during adolescence, whereas peer influences increase. Early in the study of antisocial behavior, Robins (1966) found that macro characteristics of children's peer groups, parent characteristics, and school performance, in combination, accounted for a substantial number of subsequent antisocial adolescents. For this reason, it is surprising that more data addressing the joint influence of parents and peers at different developmental stages are not available. Parent-peer models hold the most promise for guiding comprehensive intervention strategies that prevent or reduce antisocial behavior prior to adulthood.

Bronfenbrenner (1979, 1989) refers to such models as *mesosystem* models. A true mesosystem model not only incorporates the additive univariate effects into a multivariate model, thereby explaining variance in antisocial behavior, but it also assesses the interaction between the microsystems. The research reviewed in this section assesses the joint influence of parents and peers on antisocial behavior, as well as the impact of parent and peer systems on each other. Studies that incorporate these developmental questions are also included here.

Based on data collected from families and peer groups in the 1950s and 1960s, Elder (1980) found that adolescents coming from less nurturing, less positive, and less involved parent-child relationships were more likely to

become invested in a deviant peer group and to respond to the deviant group norms with like behaviors. Conversely, children who had close and positive relationships with their parents tended to select values congruent with their parents', which were often prosocial and conventional. These findings suggest that a shift may occur in adolescence, when it becomes ever more critical for parents to maintain and enhance their relationship and involvement with adolescents. Kerr and Stattin (2000) point out that, inadvertently, parents' intrusive efforts to monitor can actually undermine adolescents' willingness to self-disclose. Dishion and McMahon (1998) make a similar point, positing that parent monitoring is based on positive family relationships. Invariably, adolescents involved in problem behavior are less open about their activities than adolescents with nothing to hide, and to this extent, the exchange of information necessary for monitoring is bidirectional.

As children move toward adolescence and spend more time outside direct adult scrutiny, parental monitoring becomes an increasingly important predictor of delinquent behavior. Stoolmiller (1990) referred to this preadolescent behavior as *child wandering*, and this can be added to the list of problematic behaviors exhibited by the persistently antisocial child. Dishion et al. (2000) proposed a premature autonomy mesosystem model, which integrates an evolutionary perspective with learning theory. Adolescence is a time of rapid biosocial change, and these biological changes affect the salience and energy of peer relationships (Spear, 2000). As several ethologists have discussed, adolescence is a developmental period when peer coalitions are critical for facilitating reproduction and survival (Sameroff & Suomi, 1996). Thus, we speculated that deviant peer affiliations were an adaptation of marginalized young adolescents.

We tested the premature autonomy model with a sample of high-risk young adolescent males and females, finding that school maladaptation (peer rejection, behavior problems), poor parent monitoring, and puberty predicted deviant peer affiliation. Deviant peer affiliation and puberty were the strongest predictors of early-onset sexual intercourse and number of partners with whom the adolescents had sex at ages 15 to 16 (Dishion et al., 2000). These findings build on the groundbreaking research of Magnusson, Stattin, and Allen (1985) showing the provocative effect of early female maturation on affiliation with older deviant males. We propose that the same effect is likely to apply to males of marginal social status.

As noted earlier, mediation models seemed appropriate when considering the contribution of parent attributions in parenting models. However, nonlinear moderator models

seemed more appropriate when considering growth in antisocial behavior. The distinction also seems particularly appropriate when considering the roles of deviant peers in the socialization process. Latent growth modeling applies structural equation modeling to the analysis of longitudinal data, providing the capability to model both intercept and slope. Patterson (1993) tested a model that accounted for both aspects of child antisocial behavior as measured from fourth to eighth grade. In this model, the boy's relative ranking (i.e., intercept) over the 4-year interval was associated with parenting practices in the fourth grade, as defined by discipline (home observations) and monitoring. Linear growth in antisocial behavior, however, was independently accounted for by two factors: the child's increase in unsupervised wandering and his association with deviant peers. This model is particularly helpful because it points to the synergistic influences of parents and peers on antisocial behavior. Parenting practices account for the boy's antisocial trait, and deviant peers account for the boy's learning new and creative forms of antisocial behavior. The model provides an intuitively appealing picture of the joint influences of parents and peers in the maintenance and course of antisocial behavior in adolescents.

Parent involvement with continuous conflict seems to take its toll, as shown by the longitudinal analyses of the OYS parents (Dishion, Nelson, & Bullock, 2004). The data were collected every other year, consisting of directly observed parents and boys solving problems on videotape. Global ratings were made on the parents' use of family management skills from ages 9 to 18. We compared changes in observed family management for boys defined as early starters and those who were never involved in antisocial behavior. As can be seen in Figure 13.9, there was a slow but significant deteriorating in the practices of parents of antisocial boys. Forgatch and DeGarmo (2002) showed a similar decrease in effective parenting over a 3-year interval for an untreated comparison group of recently divorced mothers.

Next, we examined the joint influence of parent disengagement and observed deviancy training with friends on young adult antisocial behavior (Dishion, Nelson, & Bullock, 2004). As expected, the intercept of family management and deviant friendship process was correlated ($r = -.42$), and the intercept on both constructs negatively predicted growth. It was interesting that the intercept on deviant friendship process predicted parents' disengagement from monitoring, but not the reverse. This finding is consistent with our current emphasis on the critical role of peers in adolescent development. It may actually be that coalitions with deviant peers attenuate family ties, as well

Figure 13.9 Observed family management in adolescence for low- and high-risk youth.

as provide a proximal context for escalations in problem behavior. Indeed, when we entered the family management slope score with the deviant friendship process intercept score in a hierarchical regression, we found an interaction between the two constructs in predicting adult antisocial behavior. Boys whose parents disengaged and who selected deviant friends were those who were highly antisocial at age 26.

These findings provide the basis for considering hypotheses regarding the social origins of the early- and late-starter developmental trajectories. It may be that children who start early are essentially adapting to coercive, chaotic parenting practices. In this sense, negative reinforcement may be an operational mechanism. For those who start late, positive reinforcement by peers may be the operating mechanism whereby problem behavior becomes a means to establish connectedness to a peer group.

It seems that early- and late-onset delinquents may come from two different worlds. Even the contingencies (positive reinforcement versus negative reinforcement) that maintain the antisocial behavior are different. In a discriminant function analysis, the variables that differentiated early-onset arrest from late-onset were poor discipline, unemployed parents, frequent transitions, and antisocial parent behavior (Patterson & Yoerger, 2002). In young adulthood, those same variables differentiated among those who would remain or drop out of adult crime. As we discovered recently, the linkage between parents' antisocial behavior and the so-

cial processes leading to the youth's antisocial behavior may be what distinguishes the early- from late-onset trajectory. In our analysis, we found that the father's antisocial tendency was the best predictor of the youth's future involvement in deviancy training 5 years later (Dishion, Bullock, & Owen, in press). This further supports the need to consider functional dynamics at different time scales. Some youth may be primed to find and interact with a deviant peer group early on, which results in the early display of the more serious conduct problem systems and the amplification of coercive dynamics at home, until, of course, the parent gives up. Thus, the nature of the world the child lives in makes a difference at both the micro and the macro levels.

Summary

Evidence was reviewed that provides support for the hypothesis that socialization exchanges within relationships are both a cause and an outcome of antisocial behavior. Over the past 25 years, considerable progress has been made in understanding the impact of parenting practices, both in longitudinal research and in the context of longitudinal field experiments. Parenting clearly makes a difference. However, it is unrealistic to consider either parenting or peer influences in isolation. A mesosystem model that incorporates both parenting practices and peer influences helps to explain the persistence and continuance of antisocial behavior into adulthood. We need more studies that demonstrate how it is that these two systems influence each other. Peer management and structuring practices may be one of the central roles of parents in effecting long-term adjustment in their children.

Behavior Settings

In much of the research on antisocial behavior, the impact of relationships is assessed as if it occurs in a vacuum. The ecological model alerts us to the importance of the context in which these relationships are embedded. Following Glen Elder's (Elder & Caspi, 1988; Elder, van Nguyen, & Caspi, 1985) persuasive lead, we conceptualize the impact of contextual variables, such as divorce, poverty, and neighborhood, on child outcomes to be mediated by the impact on parenting practices. Elder and his colleagues demonstrated that prolonged exposure to such major stressors as the economic depression of the 1930s did, indeed, lead to negative child outcomes. The effect was mediated by the presence of an irritable father and disrupted paternal discipline practices.

Extensive use was made of Elder's mediated model when studying the impact of various contexts on child outcomes in the OYS. The findings consistently support the model. For example, divorce is associated with negative child outcomes only for those mothers whose parenting practices are disrupted (Forgatch & DeGarmo, 2002). The findings are reviewed in Patterson, Reid, et al. (1992) and Capaldi, DeGarmo, Patterson, and Forgatch (2002).

The problem of studying contextual factors that contribute to individual-level psychopathology is not new. As in the study of peer influence, the issue becomes one of contrasting selection with influence. Families often select settings, and therefore, setting factors may simply reflect vulnerability associated with maladaptation. Parenting occurs in homes, which are in neighborhoods. Peer interactions take place in neighborhoods, in schools, at the bus stop, on the street, in shopping malls, in organized activities, and in families.

There are two new developments in research neighborhood effects. In this research, it is clear that neighborhood context contributes to the early onset of antisocial behavior (Ingoldsby & Shaw, 2002). The relationship tends to be mediated by parenting practices as much as the correlation between stress, poverty, and the development of antisocial behavior (Conger, Patterson, & Ge, 1995; Conger et al., 2002; McLoyd, 1990; McLoyd & Steinberg, 1998; Patterson, 1985; Sampson & Laub, 1994).

We know that deviancy in school is related to deviancy in the home. It is also clear that children who are deviant in both settings have a poorer prognosis. In several early studies, we found that maladaptation at home and school was a particularly poor sign for children and adolescents. For example, Dishion and Loeber (1985) found that boys who were physically aggressive at home and school showed high levels of risk on mother-son coercion, deviant peer association, and maternal rejection. More recently, young adolescents identified as *externalizing* and *internalizing* at home and school were found to be at extreme risk for substance abuse, arrests, and high-risk sexual behavior 2 to 3 years later in middle adolescence (Dishion, 2000).

By and large, the correlation in antisocial behavior across the two settings is not high. There are only a few studies that have collected careful observation data in both the home and the school setting. In an analysis of consistency in coercive interaction patterns, as observed in the playground and the laboratory setting with parents, we found a coefficient of .19 (Dishion, Duncan, Eddy, Fagot, & Fetrow, 1994), statistically reliable but unimpressive. In the Wichita study, Snyder et al. (2003) observed parent-child interactions in a standardized series of laboratory

settings and sampled playground interactions with peers. Teacher ratings of aggression defined the classroom setting. A parent-child interaction composite correlated .25 with playground interactions with peers and .46 with teacher ratings of classroom behavior. The findings are in agreement with the conventional wisdom that trait behaviors generalize modestly across settings.

As discussed later in the chapter, some individuals are more sensitive to disrupted environments and therefore may show more cross-setting consistency. For example, in a study of home observation and school behavior problems, Stoolmiller (2001) found an interaction between the child's temperament (i.e., low inhibitory control) and parenting interactions in predicting long-term patterns of antisocial behavior at school. Using retrospective parent reports of child's poor self-regulation and direct observations of parent discipline, he found that inclusion of the interaction term between the two constructs accounted for growth in teacher-reported behavior problems at school from ages 9 to 14. This is a critical analysis for two reasons. First, the settings are relatively independent (home and school), and second, the model accounted for 38% of the variation in nonoverlapping constructs. The findings are quite consistent with those reported by two other investigative teams (Bates, Pettit, & Dodge, 1995; Shaw et al., 2003).

The contribution of schools to the etiology and course of antisocial behavior is likely to be much more complex than can be captured in a cross-setting consistency coefficient. To understand the contribution of schools to antisocial behavior, it is critical to examine academic failure, peer rejection, and the formation of peer groups (Patterson, Reid, et al., 1992). Our initial studies showed that most children who showed high rates of antisocial problems in the home tended to be academically below standard (Patterson, 1982). The analyses of data from the OYS showed a path coefficient of $-.57$ between a latent construct for antisocial behavior and the construct for school achievement (Patterson, Reid, et al., 1992). The Forgatch and DeGarmo (2002) review of findings from the Oregon Divorce Studies replicate this correlation between poor academic achievement and children's antisocial behavior.

As discussed earlier, there is more support than not for the idea that failure in academics and peer rejection contribute to the coalescence of deviant peer cliques over and above what would be predicted by the attraction of children who share antisocial behavior. We have referred to this process as the *confluence hypothesis* (Dishion, Patterson, & Griesler, 1994). However, the contribution of schools to the development and course of antisocial behavior may be most pronounced in early adolescents, with the advent of the mid-

dle school environment. We were able to predict the early formation of gangs in a multiethnic public school by academic failure and peer rejection (Dishion, Nelson, et al., in press). More recently, we examined the confluence hypothesis in eight middle schools in a suburban setting, with mostly European American early adolescents. Building off the work of recent studies (e.g., Laird, Jordan, Dodge, Pettit, & Bates, 2001; Rodkin, Farmer, Pearl, & Van Acker, 2000), we used both liking and rejection nominations to predict the formation of deviant peer cliques. We found that a multiplicative term of liking and rejection defined the likelihood that a young adolescent was to be submerged in a deviant peer clique in the next 2 years of middle school. As expected, growth in involvement in deviant peer cliques was associated with growth in problem behavior, using constructs that were defined by independent methods (Dishion, Light, & Yasui, 2004 paper presentation at ISSBD). Finally, there was significant variability by schools in peer rejection, deviant clique formation, and problem behavior; the three experiences were clearly concordant.

These are promising beginnings. But it is obvious that some pieces of the puzzle are missing. If schools contribute to the development and course of antisocial behavior, then it would be expected that effective school-based interventions and prevention strategies would have a profound impact. If such were the case, this would have a profound impact on public policy. The work by Kellam and colleagues (Ialongo, Poduska, Werthamer, & Kellam, 2001) does suggest that interventions targeting the school environment do have long-term effects on the development and course of problem behavior. Recent progress in the development of school interventions that promote a more organized approach to managing student behavior is particularly compelling in this regard (Crone & Horner, 2003; Sugai, Horner, & Sprague, 1999). However, these schoolwide intervention strategies have yet to be tested in a randomized trial that includes data collected in both home and school. If school aggression is eliminated, as was the case for the LIFT study (Stoolmiller, Eddy, & Reid, 2000), what are the effects on aggression observed in the home? If levels of aggression occurring in the home are dramatically reduced, what is the impact on the school behaviors? At what point in development can such effects be expected? These are the three big next-generation questions that must be answered if we are to continue in our efforts to build a theory.

Self-Regulation

As we discussed, there is a paradox inherent in the research linking self-regulation with antisocial development. On the

one hand, as hypothesized by Moffitt (1993), early-starting youth are less organized, regulated, and mutual in their social interactions with friends (Dishion, Nelson, Winter, et al., 2004; Dishion, Nelson, et al., in press). However, it is the youth who are both *antisocial* and *self-regulated* that are the most prone to continuing their deviance into adulthood. An untested assumption is that youth who become more polished and refined in manipulation are also more successful in avoiding detection for increasingly more serious crimes (burglary, robbery, drug sales). This would be a major wrinkle in the early-starting persistent hypothesis, but is quite consistent with an ecological view of adaptation (e.g., Bronfenbrenner, 1989; Hinde, 1989). Soldiers who survive the vicissitudes of war become better at killing; youth who survive the antisocial lifestyle get better at being deviant. The dynamic of self-regulated deviance certainly needs further exploration, but the idea that youth become more calloused and manipulative fits some of the literature relevant to adult psychopaths (Hare, Forth, & Strachan, 1992; Newman, Widom, & Nathan, 1985; Raine, 1993, 2002).

The majority of the literature on self-regulation, however, emphasizes individuals' ability to inhibit or avoid committing antisocial acts. To this extent, the construct itself may be vulnerable to the empirical quagmire described earlier, with global ratings of competence highly (negatively) correlated with global ratings of antisocial behavior.

There are several lines of research suggesting that measures of self-regulation are *not* redundant to the antisocial construct. Several investigators have empirically linked the concepts of resiliency, self-regulation, and problem behavior (Lengua & Sandler, 1996; Masten, Best, & Garmezy, 1990; Masten & Coatsworth, 1998; Miller & Brown, 1991; Wills & Dishion, 2004; Windle, 1990). A critical feature of resiliency at the individual level appears to be the capacity to engage in planful, goal-directed action, which includes selection of friends and partners conducive to one's goals (Haggerty, Sherrod, Garmezy, & Rutter, 1994; Rutter, 1989).

The notion of self-regulation is conceptually linked to the construct of temperament. Two decades of programmatic research on child temperament consistently reveal attentive control and inhibitory control as central to adjustment in socialization (Kohnstamm, Bates, & Rothbart, 1989). The capacity for self-control of behavior, cognition, and emotion falls under the rubric of executive attention (Rothbart, Ellis, & Posner, 2004). Recent neural imaging studies (e.g., Sowell & Jernigan, 1998) provide evidence of substantial adolescent and postadolescent brain development in frontal areas thought to serve executive

functions such as attentive control. These executive functions are largely located in the prefrontal cortex and, more specifically, the anterior cingulate cortex (ACC; Frith & Frith, 2001).

Linking neural imaging studies to pragmatic measures that assess individual differences and attentive control has been a recent goal. Posner and colleagues (Fan, McCandliss, Sommer, Raz, & Posner, 2002) developed a task under conditions of neural imaging that linked alerting, orienting, and executive attention to activity in the ACC as revealed in functional magnetic resonance imaging. The basic strategy in the attention network task (i.e., ANT) is to use perceptual conflict (i.e., Stroop) to engage various aspects of attention. The variation in reaction time is considered to be a useful index of attentive regulation, such as the ability to alert, orient to new stimuli, and deal with distractive stimuli.

From a developmental perspective, it makes sense that the form of self-regulation would vary from early childhood through young adulthood. For example, in the work by Kochanska (1993, 2002; Kochanska, Murray, Jacques, Koenig, & Vandegeest, 1996), inhibitory control is a key component of self-regulation in early childhood. However, as children adapt to new contexts such as the public school setting, other facets of self-regulation are likely to become critical. For example, as the demands increase for children to complete tasks with multiple steps, such as chores and homework, it is critical that behavior activation becomes a key component of self-regulation. In adolescence, with the introduction of free time and autonomy, it becomes critical for young people to resist temptation and stay the course on long-term objectives related to academic achievement and/or skill development. Finally, in young adulthood, a key component of self-regulation is the selection and identification of social and economic contexts that fit well with one's social, motor, and intellectual abilities.

The work on self-regulation and problem behavior is limited to understanding the development and course of adolescent drug use. In this work, the construct of self-control has been invoked as an individual characteristic that reduces the likelihood of developing a drug and alcohol problem once exposed (Miller & Brown, 1991; Wills & Dishion, 2004). In understanding substance use, self-regulation is seen as a moderator variable, explaining those youth who do not develop serious drug and alcohol problems given exposure by peers and spouses.

As discussed earlier, a process model for the development of antisocial behavior should describe the mechanism accounting for the normative decreases in overt antisocial behavior, the age-crime curve, desistence from antisocial

behavior in late adolescence, and the fact that many youth exposed to deviant peer influences (i.e., growing up in the same neighborhoods and schools) are unaffected. In fact, if one looks at the data in even the highest risk settings, it is clear that 40% to 50% do not develop any signs of problem behavior; they are the zeros in our skewed distributions of problem behavior. Statistical innovations that allow for the formation of developmental trajectories (e.g., Muthén & Shedden, 1999; Nagin & Tremblay, 1999) always yield a large low-risk group (e.g., Connell et al., in press).

If self-regulation is a construct of empirical utility for explaining the development of antisocial behavior, then it should account for unique (nonredundant) variance, or at least function as a moderator variable. That is, self-regulation may explain why some children do *not* become antisocial given exposure to the right environmental conditions.

The literature establishing interaction effects on any dimension of child self-regulation and problematic environments is underdeveloped at this stage. If one focuses on the genetic underpinnings of self-regulation, there is some evidence supporting complex interaction between pervasive environmental experience and biological predisposition (see Caspi et al., 2002; Cloninger & Gottesman, 1987; Deater-Deckard, in press; Leve et al., 1998; Maccoby, 2000; Neiderhiser, Reiss, & Hetherington, 1996; Rhee & Waldman, 2002; Taylor, Iacono, & McGue, 2000). Perhaps most noteworthy in these studies is work reported by Caspi et al. showing an interaction among genetic vulnerability, abusive parenting environments in childhood, and propensity to violence in adulthood. However, the amount of variation accounted for by the interaction term is limited. This elaborate and innovative study requires further replication and extension.

Moderation Hypothesis

In our recent research on understanding and preventing adolescent problem behavior, we assessed self-regulation among adolescents at ages 15 to 17 years. We used two strategies for the assessment of self-regulation. The first was the Rothbart (Rothbart et al., 2004) measure of temperament extended into adolescence. This measure includes two scales assessing effortful attention control, otherwise referred to as attention control. The items on these scales are not simply the reverse of antisocial behavior, including behaviors specific to the ability to attend, persist in tasks, and regulate oneself in the context of competing demands. In addition, we assessed the youth's ability to alert, orient, and exercise executive control in the context of a computerized attention task referred to as the ANT. To consider the role of self-regulation in the development of problem be-

havior, we formulated three developmental groups based on longitudinal data from six yearly assessments. Both male and female adolescents following early- ($n = 39$) and late-starting ($n = 38$) and successful ($n = 37$) pathways were selected for the study.

The assessment of temperament included youth and parent report. The effortful attention control factor comprises the following subfactors: activation control, attention, and inhibitory control. The ANT assessment involves a flanker conflict paradigm that includes a central target arrow flanked on either side by arrows pointing in either the same (congruent) or the opposite (incongruent) direction of the target arrow. Incongruent trials generally produce longer reaction times than congruent trials, because the presence of incongruent flanker arrows causes a degree of attention conflict. The task allows calculation of individual difference scores in attention control. The score is computed via subtraction of congruent flanker trial reaction times from incongruent flanker reaction trials.

Unexpectedly, we found no covariation between the youth's performance on the ANT conflict task with either child or parent report of self-regulation. However, self-regulation was correlated moderately between parent and child report ($r = .34$). Therefore, we included only parent and child report of attention control as a measure of the youth's ability to self-regulate.

Figure 13.10 provides an overview of the findings. As can be seen, there is an orderly progression from less to more self-regulation when considering early starters, late starters, and successful students, respectively. Also of interest is the normality of the distribution across the two samples. The child report shows less variation than the parent report; however, both show increasing self-regulation associated with the developmental onset of antisocial behavior and the probable prognosis (Moffitt, 1993; Patterson & Yoerger, 1993).

If self-regulation is a resiliency factor, then youth who are highly self-regulated are likely to be less influenced by deviant peers. A general construct for the youth's antisocial behavior was formulated on self-reported delinquency and antisocial behavior and substance use. As revealed in a hierarchical linear regression, both self-regulation and deviant peer involvement significantly predicted antisocial behavior in middle adolescence. It is relevant that self-regulation added to the prediction accounting for 43% of the variation in antisocial behavior (total $R^2 = .43$ with both predictors). In a second step, the interaction between self-regulation and deviant peer involvement was entered into the equation. A significant interaction was found between self-regulation and deviant

Figure 13.10 Toward a single model for the development of antisocial behavior.

peer involvement. Plotting of the interaction term revealed a tendency for youth who were high in self-regulation to be less affected by the influence of deviant peers on antisocial behavior. In contrast, for youth low in self-regulation, the level of antisocial behavior varied quite dramatically as a function of their deviant peer involvement (T. Gardner & Dishion, 2005).

These data show some support for the construct of self-regulation as a resiliency factor in the development of antisocial behavior. Significant methodological problems require attention, however, before the research can be considered conclusive. First, the lack of correlation between the attention measure of self-regulation and both parent and adolescent reports of attention control requires some explanation. One likely explanation is that early in development, children's ability to control attention in a laboratory setting may, in fact, predict parent ratings of self-regulation. By adolescence, self-regulation may become more domain-specific. For example, the ability to regulate oneself in detailed, tedious tasks may be highly influenced by the content and practice with similar tasks (e.g., videogames, writing, math). Second, we used the ANT measure of attention control in the home and the research center, using a variety of computers. The context of the task may require more control to accurately assess individual differences in attention control. Third, a more rigorous test of the resiliency hypothesis is to show longitudinal, interaction effects. That is, youth with higher levels of self-regulation who were also exposed to pathogenic

Figure 13.11 Self regulation by timing of the development of antisocial behavior in Project Alliance sample.

peer and parenting environments do not escalate in antisocial behavior.

Despite these barriers, we propose a hypothesis linking self-regulation to antisocial behavior, which is summarized in Figure 13.11. We hypothesize that self-regulation *moderates* the relationship between relationship dynamics, such as coercive family interaction or peer deviancy training, and the timing and severity of child and adolescent antisocial behavior. Because the parenting environment of the early-starting group is disrupted, these youngsters are less able to navigate their own future. Late starters, however, benefit from early family management and therefore have higher levels of self-regulation. Consistent with recent work in neuroscience, we see self-regulation as linked to growth of attention networks that empower behavior inhibition and that early childhood is an important time for the development of this ability (Rothbart & Posner, Chapter 11, this *Handbook*, Volume 2).

Particularly important for further investigation are the family management underpinnings of self-regulation in children. One can see that setting limits and behavior management of children require the child's exercise of behavior inhibition and therefore growth in self-regulation. This hypothesis requires more attention, in particular, in the context of intervention trials that address family management. Do improvements in family management in early childhood, a time critical for the development of self-regulation, have long-term effects on adolescent problem behavior? The work by Olds and colleagues (1997) suggests it does. More to the point, do interventions that specifically target self-regulation in children have independent effects on the prevention of antisocial behavior, as suggested by the work of Lochman and Kazdin (e.g., Kazdin et al., 1992; Lochman & Wells, 1996)?

If these research hurdles are surpassed, the mechanisms linking socialization processes and the acquisition of rule-

governed behavior need explication. In the learning theory literature, Hayes and colleagues (Hayes, Gifford, & Ruckstuhl, 1996; Hayes & Hayes, 1992; Hayes, Hayes, Sato, & Ono, 1994) provide the most comprehensive account of the role of language in human learning. The ability to follow rules is built on the acquisition of a linguistic frame that presumes "it's worth it to be prosocial." The framework is theoretically rich but has yet to be linked to observations of family living and individual differences in child and adolescent self-regulation and engagement in antisocial behavior.

SUMMARY AND IMPLICATIONS

Over the past 10 years, enormous progress has been made in understanding the development of antisocial behavior. Figure 13.12 is a summary of empirical linkages that have been established, as well as those that, at this writing, are tentative and require further testing. Four points are emphasized in this summary:

1. Although antisocial behavior is a robust, psychometrically sound construct, it is useful to understand developmental process and gender differences to consider specific forms of antisocial behavior, including distinctions between overt (physical and verbal aggression, reactive aggression) and covert (proactive aggression, relational aggression, stealing, etc.).
2. Parent-child interaction and management dynamics play a significant role in establishing the child's trajectory into antisocial behavior in early and middle childhood as well as adolescence, and intervention research reveals that targeting parenting practices produces reductions in child and adolescent risk.

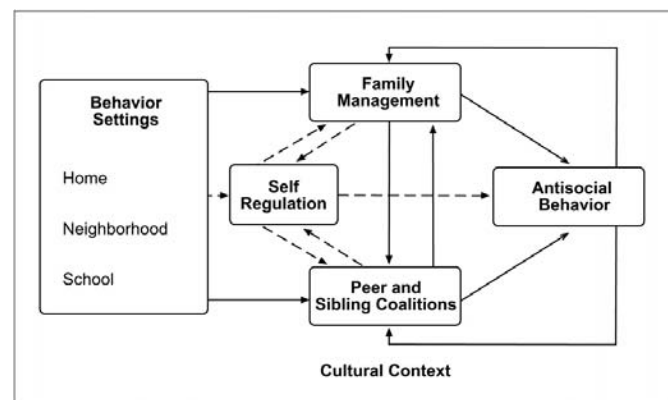

Figure 13.12 Empirical summary for the development and ecology of antisocial behavior.

3. Peer influences are now a dominant theme in the etiology of antisocial behavior, beginning in early childhood and increasing during adolescence. Intervention research, inadvertently, underscores the power of peer contagion in amplifying adolescent problem behavior.
4. Neuroscience and developmental research are converging at understanding the basic brain-behavior linkages that explain the emergence and growth of executive control and, ultimately, self-regulation. Future research in this area might lead to a theory of normative socialization, resilience, and differential prognosis associated with age of onset of antisocial behavior and, perhaps, other forms of psychopathology.

In Figure 13.12, the solid arrows represent hypotheses that are supported by previous longitudinal and intervention research, and the dotted lines are hypotheses that require further testing and development. In contrast to 10 years ago, the field has extended research to children of different cultural and racial groups. At some point, isolating the mechanisms that explain contextual differences in child and adolescent problem behavior remains a scientific need. Similarly, process-oriented research that considers the interplay between biology and family and peer dynamics, especially around developmental transitions such as adolescence, is still needed.

At this stage, we assert that enough is known to fill in a rough sketch of the antisocial developmental process, especially for understanding boys who exhibit a persistent life course pattern. The development of more serious and chronic antisocial behavior seems to follow a stage-like progression, consistent with notions of hierarchical integration. In the coercion model, the practice of aversive pain control in the family undermines relationships and entrains response patterns that facilitate the emergence of antisocial behavior in other settings, such as schools (with teachers and peers). Eventually, the antisocial behavior is less reactive, and children develop peer groups that encourage problem behavior and even plan and collude to commit antisocial acts. As shown in the classic analyses by Jones, Reid, and Patterson (1975), deviant children are, indeed, less responsive to setting differences. They react coercively over time and across settings.

This style of interacting with peers becomes automatic and highly stable across adolescence, providing a basis for ongoing shopping for relationships and settings that support previously established behaviors and patterns. If unabated, parents eventually give up and peers take over, accounting for the persistence of adolescent problem behaviors into adulthood. Those who start early, then, ac-

tively construct social experiences that minimize their pain and maximize their gain. In the short run, such social optimization functions well. Unfortunately, in the long run, the antisocial pattern undermines the maturation into adult roles and the formation of new families. Selection of an antisocial spouse could permanently cement the developing adult in a life of maladaptation through criminal behavior, incarceration, and ever more coercive family relationships (Quinton, Pickles, Maughan, & Rutter, 1993; Woodward, Fergusson, & Horwood, 2002).

One of the barriers the present authors continually confront is how to integrate positive aspects of development with our understanding of the biological and environmental influences in antisocial development. We project that the next 10 years will be marked by progress on this issue. In particular, we consider a convergence of findings on understanding young children's development of emotional regulation, attentional control, tendency to comply with adult requests, and prosocial behavior. Eisenberg and Fabes (1998) provide a comprehensive review of this rapidly growing literature.

The promise of the developmental psychopathology perspective is to continue to focus on the intervention implications of etiologic research (Cicchetti & Toth, 1992). An explicit strategy for the programmatic integration of etiologic research and intervention trials has been proposed (Patterson, Reid, et al., 1992). We can suggest alternative intervention strategies to reduce or prevent antisocial behavior (Dishion & Stormshak, in press). The key idea, however, is not only to get intervention effects (i.e., reductions in antisocial behavior), but to document how the intervention effects are achieved—that is, to understand the process of change (Dodge, 1993). Such an approach makes developmental psychopathology a dynamic science and, as applied to the understanding and prevention of child and adolescent antisocial behavior, worthy of further pursuit.

Schizophrenia is a severe mental illness afflicting about 1% of the population (T. D. Cannon, 1996). Its characteristic symptoms include hallucinations, delusions, disorganized speech and thought, and abnormalities in emotional expression and motivation (American Psychiatric Association, 1994). Throughout most of the twentieth century, our understanding of the origins and developmental course of this disorder was substantially influenced by Emil Kraepelin (1918), who proposed that Schizophrenia is a deteriorating brain disorder similar in natural history to Alzheimer's disease, but with onset in early adult life. Although Kraepelin himself speculated that some cases were likely due to early insults that caused cerebral maldevelopment, this view of Schizophrenia as a neurodegenerative disorder persisted.

Over the past 25 years, there has been a major shift toward a neurodevelopmental model of Schizophrenia which posits that the neural underpinnings of the disorder arise primarily during early central nervous system development (see left section of Figure 14.1; T. D. Cannon, 1997; Wein-

berger, 1987). Support for this theoretical viewpoint comes from several lines of evidence. Numerous prospective studies have revealed associations between prenatal and perinatal complications and elevated risk for Schizophrenia, thus implicating adverse events during early life as contributing to the development of the disorder. Additionally, a large body of evidence documents the presence of subtle deficits in cognition and behavior during childhood among individuals who ultimately develop Schizophrenia as adults, suggesting that signs of brain compromise are present long before illness onset (Bearden et al., 2000; T. D. Cannon, Rosso, et al., 2000; Rosso, Bearden, et al., 2000). Moreover, postmortem neuropathology studies have in general failed to detect evidence of a dementia-like degenerative process in Schizophrenia (Arnold & Trojanowski, 1996); rather, the reductions in cortical gray matter volume in these patients appear to be accounted for largely by reductions in the degree of dendritic arborization and density of synaptic contacts on pyramidal neurons (i.e., reductions in neuropil volume; Glantz & Lewis, 2000; Selemon &

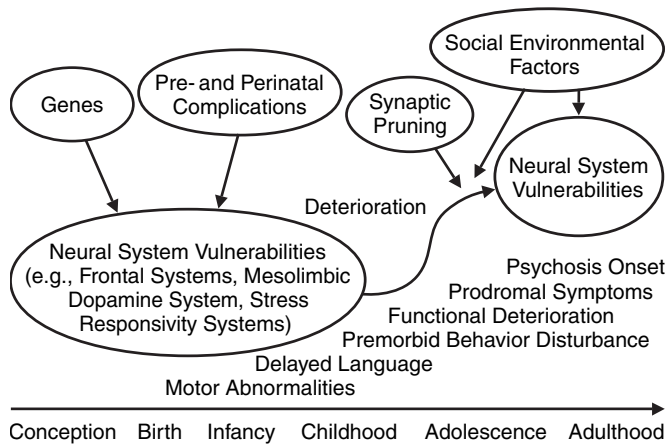

Figure 14.1 Theoretical framework illustrating early and late neurodevelopmental influences in the etiology and pathogenesis of Schizophrenia.

Goldman-Rakic, 1999), findings that suggest involvement of cellular plasticity mechanisms rather than neuronal degeneration per se.

Nevertheless, the notion that the risk factors for Schizophrenia emerge exclusively during prenatal and perinatal brain development begs the question of why formal diagnostic symptoms and signs of the disorder do not typically manifest until late adolescence and early adulthood. Indeed, there is a remarkable consistency in age-at-onset distributions for Schizophrenia from around the world, implicating the late adolescent/early adult period as the peak period of risk for onset (Jablensky et al., 1992). Adolescence also represents a period of active brain development, during which increases in neuronal efficiency are accompanied by a reduction (i.e., pruning) of excess synapses and by myelination of axonal connections in regions critical for higher-order cognition, particularly the prefrontal cortex (Huttenlocher, 1979). Together, these considerations have led several theorists to suggest that processes associated with adolescent brain development may play a role in the pathogenesis of Schizophrenia (see right section of Figure 14.1; Feinberg, 1990; Hoffman & McGlashan, 1997). Interestingly, some structural magnetic resonance imaging (MRI) studies have observed progressive gray matter reductions in first-episode patients with Schizophrenia, with a leveling off after the first few years of active illness (Gur et al., 1998; Thompson et al., 2001). Although the sources of this progression remain controversial, given that most of the first-episode patients who have been scanned in these studies are in the adolescent to early adult period, it is possible that this progression reflects a process associated with the mechanisms underlying synaptic pruning. Such

processes may be overly aggressive in individuals predisposed to developing Schizophrenia (e.g., due to a Schizophrenia-related defect in synaptic plasticity mechanisms), or these processes may be normal but interact with previously existing compromises of brain structure in winnowing neuronal connectivity to below some hypothetically critical threshold. To evaluate these theoretical notions in samples in which adolescent brain developmental processes can be disambiguated from the influences of medication and active psychosis, a new research paradigm has recently been developed, ascertaining individuals who are initially showing symptoms consistent with a high risk for imminent onset of psychosis (i.e., prodromal patients) and following them over time to characterize the course of neurobiological change among those who develop full-blown psychosis and to elucidate predictors of this outcome (T. D. Cannon et al., 2003; Yung & McGorry, 1996).

This chapter reviews and evaluates evidence bearing on the questions of whether and how both early (i.e., pre- and perinatal) and late (i.e., adolescent) neurodevelopmental influences may be involved in the etiology and pathogenesis of Schizophrenia. We first describe briefly the various neural disturbances that have been detected in Schizophrenia, followed by an analysis of studies investigating the roles of genetic and nongenetic factors in these brain abnormalities. These studies provide a useful framework for hypothesis generation concerning the timing of onset and course of brain abnormalities in Schizophrenia, as certain of these brain abnormalities appear to be reflective of an inherited vulnerability state and are thus likely to emerge prior to illness onset and to be fairly stable after their initial appearance, whereas other abnormalities are unique to (or more severe in) individuals who manifest the illness phenotype and may thus first appear or significantly worsen as one moves beyond an inherited vulnerability state to a fully symptomatic psychotic state. We then turn to a review and analysis of the various literatures bearing more directly on the question of the timing of onset and course of brain abnormalities in Schizophrenia. The principal conclusions that can be reached from this review are that (1) the case for involvement of early neurodevelopmental influences in the etiology and pathogenesis of Schizophrenia is consistent and compelling, including evidence from human epidemiological studies, prospective studies of birth cohorts and samples at risk, postmortem neuropathology studies, and experimental studies using animal models; and (2) the case for involvement of later neurodevelopmental processes is still largely circumstantial, but at minimum such processes appear likely to influence the timing of onset of diagnostic symptoms and signs. We conclude this

chapter with an updated version of the neurodevelopmental hypothesis of Schizophrenia, specifying a number of ways in which particular sets of early and late influences might interact in determining the timing of onset and course of the disorder.

NATURE AND SOURCES OF BRAIN ABNORMALITIES IN SCHIZOPHRENIA

In the past 2½ decades, significant progress has been made in the characterization of brain abnormalities in Schizophrenia and in elucidating the contributions of genetic and nongenetic influences to these abnormalities. Disturbances in prefrontal and temporolimbic systems and their interconnections are particularly prominent in this disorder (J. D. Cohen & Servan-Schreiber, 1992; Grace, Moore, & O'Donnell, 1998; Gray, Feldon, Rawlins, & Hemsley, 1991). In neuropsychological studies, where patients with Schizophrenia have been found to show performance deficits on nearly all measures of functioning, working memory, attention, abstraction, episodic learning and memory, and language functions appear to be more severely affected (T. D. Cannon, Huttunen, et al., 2000; Saykin, Shtasel, Gur, & Kester, 1994). These findings have been corroborated by evidence of abnormal physiologic activity (i.e., altered blood flow) in prefrontal and temporal lobe regions in patients with Schizophrenia during performance of tests assessing these domains of functioning (e.g., Berman, Torrey, Daniel, & Weinberger, 1992; Callicott et al., 1998; Yurgelun-Todd et al., 1996). At the structural-anatomical level, patients with Schizophrenia show a variety of volumetric changes throughout the brain, including reduced cortical, hippocampal, and thalamic volumes and increased sulcal and ventricular volumes (Pfefferbaum & Marsh, 1995). Some neuroimaging work indicates a relatively greater degree of reduction in frontal and temporal cortical volumes compared with posterior cortical volumes (T. D. Cannon, van Erp, et al., 1998).

Based on postmortem evidence of decreased thickness of the prefrontal cortex without a reduction in the number of cell bodies (Selemon, Rajkowska, & Goldman-Rakic, 1995; Selemon, Rajkowska, & Goldman-Rakic, 1998), it has been suggested that a reduction of interneuronal neuropil underlies in vivo MRI findings of cortical gray matter reduction in Schizophrenia (Selemon & Goldman-Rakic, 1999), a prediction that has been confirmed by observations of reduced dendritic spine density on prefrontal cortical pyramidal neurons (Glantz & Lewis, 2000). This pattern implies a disruption in cellular plasticity mecha-

nisms rather than neuronal degeneration per se, an interpretation that is also supported by lack of gliosis, or the scarring associated with degeneration of cortical neurons, in the brains of patients with Schizophrenia, a pattern that would be expected to result from an active neurodegenerative process (Bogerts et al., 1993; Casanova & Kleinman, 1990). This interpretation is also supported by findings of cellular positioning abnormalities that are consistent with disturbances of neuronal migration during gestation (Akbarian, Bunney, et al., 1993; Akbarian, Vinuela, et al., 1993; Arnold, Hyman, Van Hoesen, & Damasio, 1991; T. D. Cannon & Mednick, 1993; Jakob & Beckmann, 1986; Kovelman & Scheibel, 1984; Weintraub, 1987). Although these latter findings clearly imply that risk factors for Schizophrenia are operative in utero, it is not yet known whether the cellular positioning abnormalities play a role in the pathophysiology of Schizophrenia or whether they are related to the gross morphological findings such as gray matter reduction.

Liability-Related versus Disease-Specific Brain Abnormalities

A question of major importance is whether some of the brain abnormalities associated with Schizophrenia are shared by the nonpsychotic first-degree relatives of these patients. Such a pattern could occur given the complexity of the inheritance of the disorder, in which multiple genes of small effect and a nontrivial environmental component aggregate to increase risk for phenotypic expression (T. D. Cannon, Kaprio, Lonnqvist, Huttunen, & Koskenvuo, 1998). That is, many first-degree relatives of Schizophrenia patients would be expected to carry one or more genes in a predisposing configuration but remain clinically unaffected.

There are now several studies demonstrating that unaffected biological relatives of patients with Schizophrenia display qualitatively similar, but quantitatively milder, neuropsychological impairments when compared with normal controls, even after accounting for substance abuse and other psychiatric diagnoses (T. D. Cannon, Huttunen, et al., 2000; Faraone et al., 1999; Park, Holzman, & Goldman-Rakic, 1995). Such findings support the view that these deficits are reflective of a diathesis for Schizophrenia, rather than resulting from the disease process or pharmacological intervention. T. D. Cannon et al. (1994) found that patients with Schizophrenia and their unaffected siblings showed similar patterns of deficit with regard to verbal memory, abstraction, attention, and language functions. Similarly, Touloupoulo, Rabe-Hesketh, King, Murray, and Morris (2003) showed that healthy rel-

atives of patients with Schizophrenia exhibited deficits on verbal memory tasks, and Staal et al. (2000) reported frontal lobe impairment among unaffected siblings of patients with Schizophrenia. Other studies have reported attentional impairments among parents of patients with Schizophrenia (Michie et al., 2000).

Widespread neuropsychological deficits appear to be more severe among patients and relatives in multiply affected families. In the UCLA Family Study, normal control participants from the community with a family history of Schizophrenia had significantly poorer general intelligence, expressive and receptive vocabulary abilities, poorer visual-motor coordination, and slower motor speed than community controls without such a family loading (Asarnow et al., 2002). Additionally, Faraone et al. (2000) found that relatives from multiplex families (as defined by two or more first-degree relatives with Schizophrenia) had significantly lower scores on measures of estimated intelligence and verbal and visual recall than relatives from simplex families. Such findings support the hypothesis that impaired information processing aggregates among family members of patients with Schizophrenia and may serve as an indicator of genetic vulnerability to the disorder.

Findings of neuroanatomic abnormalities among unaffected relatives of patients with Schizophrenia may also be reflective of underlying genetic influences. Evidence from structural MRI studies of healthy relatives of patients with Schizophrenia have revealed global volumetric deficits (T. D. Cannon, van Erp, et al., 1998) and ventricular enlargement (Reveley, Reveley, Clifford, & Murray, 1982), as well as more specific structural anomalies. In a study involving a Helsinki birth cohort, significant reductions in frontal and temporal gray matter volumes and significant increases in the corresponding cerebrospinal fluid (CSF) regions were observed in both patients and their full siblings. In contrast, ventricular CSF volume increases and white matter reduction were apparent only among probands as compared to their siblings and unrelated controls (T. D. Cannon, Kaprio, et al., 1998). Reduced gray matter volume has been found among unaffected relatives outside the period of risk (Seidman et al., 1997, 1999; Suddath, Christison, Torrey, Casanova, & Weinberger, 1990), indicating that these gray matter reductions may be a stable vulnerability factor in relatives of Schizophrenia patients. Additionally, Seidman et al. (2002) found that relatives of patients with Schizophrenia, particularly those from multiplex families, had significantly smaller left hippocampal volumes as compared to matched controls. In these families, hippocampal volumes did not differ between patients with Schizophrenia and their nonpsychotic relatives.

In a recent functional MRI (fMRI) study, an N-back working memory task was employed to assess working memory-related cortical physiology in unaffected siblings of patients with Schizophrenia (Callicott et al., 2003). In this study, siblings showed an exaggerated physiological response in the right dorsolateral prefrontal cortex that appeared qualitatively similar to that seen in earlier fMRI studies of patients with Schizophrenia, indicating a primary physiological abnormality in prefrontal circuitry in individuals at elevated genetic risk for Schizophrenia without manifest cognitive abnormality. In addition, abnormal activation patterns in prefrontal and parietal regions during spatial working memory task performance have been reported in children of Schizophrenia patients (Keshavan et al., 2002).

Neurocognitive and neuroimaging studies of twins discordant for Schizophrenia allow for the separation of genetic and nongenetic contributions to the brain abnormalities associated with the illness. Because healthy monozygotic (MZ) and dizygotic (DZ) cotwins of patients with Schizophrenia differ by a ratio of 2:1 with regard to genetic liability for the disease, it is possible to test whether degree of cognitive or neuroanatomical deficit increases with genetic proximity to a proband. Further, because discordant MZ cotwins are 100% genetically identical, any abnormalities that are unique to or more severe in the affected compared with unaffected cotwins must be nongenetic in origin (M. Cannon, Jones, & Murray, 2002). A study of an epidemiologically ascertained sample of Finnish twins revealed that impaired performance on tests of spatial working memory and structural abnormalities in prefrontal brain regions varied in a dose-dependent fashion with degree of genetic loading for Schizophrenia. Specifically, MZ unaffected cotwins were significantly more impaired than DZ unaffected cotwins, who in turn were significantly impaired compared to control subjects (M. Cannon et al., 2002; T. D. Cannon, Huttunen, et al., 2000; Glahn et al., 2002). In contrast, deficits in long-term memory and anatomical changes in the hippocampus and adjacent temporal cortex were specifically more pronounced in patients compared with their own healthy MZ cotwins, indicating that nongenetic, disease-related factors must be involved in these abnormalities (T. D. Cannon, Huttunen, et al., 2000).

Given the substantial body of evidence indicating impairments in brain structure and function in relatives of patients with Schizophrenia, it should be possible to identify specific genes that underlie these disturbances. As one example, T. D. Cannon et al. (in press) examined a series of haplotype blocks of single nucleotide polymorphic (SNP)

markers from a segment of chromosome 1q42 spanning the Disrupted-In-Schizophrenia-1 (DISC1) and Translin-Associated Factor-X (TRAX) genes, using samples of Finnish twin pairs concordant and discordant for Schizophrenia and healthy control twins. Recessive transmission of a common 3-SNP haplotype incorporating markers near a translocation breakpoint of DISC1 and dominant transmission of a rare 4-SNP haplotype incorporating markers from both the DISC1 and TRAX genes were significantly more common among individuals with Schizophrenia. These haplotypes were also associated with several quantitative endophenotypic traits previously observed to covary with Schizophrenia and genetic liability to Schizophrenia, including impairments in short- and long-term memory functioning and reduced gray matter density in the prefrontal cortex, as demonstrated using a population-based brain atlas methodology. Thus, specific alleles of the DISC1 and TRAX genes on 1q42 appear to contribute to genetic risk for Schizophrenia through disruptive effects on the structure and function of the prefrontal cortex and other brain regions, effects that are consistent with their production of proteins that play roles in neurite outgrowth, neuronal migration, synaptogenesis, and glutamatergic neurotransmission.

In the remaining sections, we evaluate the various lines of evidence bearing on the question of the sources, timing of onset, and course of brain abnormalities in Schizophrenia, dividing our consideration of these studies into those that implicate early developmental processes and those that suggest involvement of later developmental processes. Based on the foregoing, in general, one would expect that deficits associated with an inherited diathesis to Schizophrenia, such as structural and functional abnormalities of the prefrontal cortex, would be present before onset of illness and thus may be related to causal risk factors arising from early in life, whereas deficits that are more severe in the affected compared with unaffected MZ cotwins, such as structural and functional abnormalities of the medial temporal lobe, may be influenced by both early risk factors and those occurring more proximally to onset of formal diagnostic symptoms and signs.

THE CASE FOR INVOLVEMENT OF EARLY NEURODEVELOPMENTAL PROCESSES IN SCHIZOPHRENIA

There is now an accumulation of evidence that subtle indicators of disturbance are present long before illness onset in individuals who ultimately develop Schizophrenia. Here

we review these various lines of evidence; specifically, we examine the role of prenatal and perinatal complications in Schizophrenia, and evidence from high-risk studies examining early neurodevelopmental deviance in genetically vulnerable individuals.

The Role of Prenatal and Perinatal Complications in the Development of Schizophrenia

Of all early environmental factors proposed to play a role in the etiology of Schizophrenia, prenatal and perinatal complications, particularly those associated with fetal hypoxia, appear to be most robustly associated with increased risk for the disorder. Fetal hypoxia appears as a risk factor in a larger proportion of the cases (30% to 40%) than all forms of pregnancy complications (including viral exposure) and signs of fetal maldevelopment (T. D. Cannon, 1997). Complications associated with fetal hypoxia are also of interest because fetal oxygen deprivation represents a plausible mechanism for explaining much of the structural pathology of the brain detected in neuroimaging studies of adult patients with Schizophrenia (T. D. Cannon, 1997). For example, in an MRI study of a Helsinki birth cohort, we found that a history of fetal hypoxia was associated with significant decreases in gray matter density in both prefrontal and temporal lobe regions among patients with Schizophrenia and their healthy siblings, but not in controls at low genetic risk for the disorder, and more so in the patients than in their siblings (T. D. Cannon, van Erp, & Glahn, 2002). This pattern appears to be consistent with a genotype-environment interaction, in which hypoxia-related obstetric complications represent random environmental events, which may add to or multiply the risk for phenotypic expression of Schizophrenia when they occur in a genetically vulnerable individual.

The hippocampus in particular is acutely vulnerable to hypoxic-ischemic damage (Vargha-Khadem et al., 1997; Zola & Squire, 2001). One twin study showed that, among MZ twins discordant for Schizophrenia, relatively small hippocampi in the ill twin were significantly related to labor-delivery complications and to prolonged labor, both risk factors associated with fetal oxygen deprivation (McNeil, Cantor-Graae, & Weinberger, 2000). Van Erp et al. (2002) found that Schizophrenia probands who experienced fetal hypoxia have smaller hippocampal volumes than those who did not, a difference not noted among unaffected siblings and healthy comparison subjects. Moreover, hippocampal volume differences occurred in a stepwise fashion with each increase in genetic load for Schizophrenia,

suggesting that, in patients with Schizophrenia spectrum disorders, hippocampal volume is influenced in part by Schizophrenia susceptibility genes, as well as an interaction of these genes with fetal hypoxia.

At the cellular level, the neural sequelae of hypoxia vary in severity from alterations in neurite outgrowth to neuronal cell death (Nyakas, Buwalda, & Luiten, 1996). In the former case, immature neurons may survive the hypoxic insult but still have a compromised elaboration of synaptic interconnections (Nyakas et al., 1996). More recent evidence from animal studies indicates that sublethal hypoxia results in global dysynchrony in brain maturation programs due to profound loss of coordinate regulation of neuronal gene transcription (Curristin et al., 2002). In a mouse model, chronic sublethal hypoxia resulted in alteration of 38% of genes subserving synaptic function, maturation, and neural transmission. Genes involved in myelination, glial maturation, and cytoskeletal organization were also affected, leading to retardation of synapse formation and reduction of cytoskeletal systems needed to form neuritic processes and synaptic structures. In addition, fetal hypoxia leads to up-regulation of stress and hypoxia response pathways, which may further retard neuronal maturation. Intriguing findings come from a rat model of Schizophrenia, in which direct lesions of the hippocampus early in life were found to produce deficits in prepulse inhibition, enhanced sensitivity to stress, and differential response to amphetamine, all of which do not become apparent until the postpubertal period (Lipska & Weinberger, 2002). Further, these investigators found that even transient inactivation of the ventral hippocampus during a critical period of development may be sufficient to disrupt normal maturation of the prefrontal cortex and trigger behavioral changes comparable to those observed in animals with permanent excitotoxic hippocampal lesions (Lipska & Weinberger, 2002).

Evidence for Cognitive, Motor, and Behavioral Impairment in Infancy and Childhood

Central to the neurodevelopmental hypothesis of Schizophrenia (Weinberger, 1987) is the identification of developmental anomalies preceding overt clinical symptoms of the disorder (M. Cannon et al., 2002; Weinberger, 1987). Retrospective studies, as well as high-risk studies of the offspring of parents with Schizophrenia, have consistently demonstrated the existence of cognitive impairment and behavioral and neurobiologic abnormalities long before the onset of Schizophrenia. Such studies offer substantial evidence that such early events may be less quiescent and more function-

ally apparent than was previously believed. Although the majority of patients with Schizophrenia show no signs of outright psychotic symptomatology until adolescence or early adulthood, there is substantial evidence that the pathologic processes that predispose to the disorder are evident earlier in life in more subtle forms.

In the domain of cognitive development, one meta-analysis of the high-risk literature (Aylward, Walker, & Bettes, 1984) revealed that preschizophrenic children showed deficits on standard IQ tests in comparison with matched groups of peers or siblings who did not develop psychiatric illness. Moreover, such deficits were shown to predict an early-onset form of Schizophrenia with poor prognostic features. Similarly, longitudinal high-risk studies have consistently found children of parents with Schizophrenia to perform more poorly on neuropsychological tests than children of parents with no history of psychiatric illness (Asarnow & MacCrimmon, 1978; Bergman & Walker, 1995; Fish, 1987; Goodman, 1987; Hallett, Quinn, & Hewitt, 1986; Landau, Harth, Othnay, & Sharfhertz, 1972; Lifshitz, Kugelmass, & Karov, 1985; Marcus, Hans, Auerbach, & Auerbach, 1993; Mednick & Schulsinger, 1964; Sameroff, Seifer, Zax, & Barocas, 1987; Schreiber, Stolz-Born, Kornhuber, & Born, 1992; Sohlberg, 1985; Weintraub, 1987). Such studies have shown that children with an elevated risk for Schizophrenia exhibit deficits in attention (Erlenmeyer-Kimling & Cornblatt, 1978; Weintraub, 1987), language (Gruzelier, Mednick, & Schulsinger, 1979; Hallett et al., 1986; Harvey, Winters, Weintraub, & Neale, 1981), learning and memory (Driscoll, 1984; Klein & Salzman, 1984; Rutschmann, Cornblatt, & Erlenmeyer-Kimling, 1980), and other information-processing domains (Erlenmeyer-Kimling & Cornblatt, 1987).

Early receptive (M. Cannon et al., 2002) and expressive (Bearden et al., 2000) language abnormalities are a robust finding among retrospective studies of individuals with Schizophrenia. Premorbid impairments of language production and comprehension are particularly striking in childhood-onset Schizophrenia (Hollis, 1995; Nicolson et al., 2000), suggesting that there may be a specific link between very early onset cases and impairment in the processes underlying language development. This notion is supported by a follow-back study of patients with childhood-onset Schizophrenia (Asarnow, 1999) showing that nearly 80% of the sample exhibited gross deficits in early language development. However, at follow-up during late childhood, these children performed within the expected range on multiple tests of language function, indicating that these skills are delayed but are not static neuropsychological deficits.

In contrast, attentional deficits may represent a trait marker of vulnerability to Schizophrenia. The New York High Risk Project has followed children at risk for Schizophrenia and affective disorder (by virtue of having an affected parent) for over 30 years with neurocognitive, behavioral, and clinical measures. In this study, impairments in attention and short-term memory were detectable by a mean age of 9 in children at high risk for Schizophrenia, a time when subjects were free of any overt behavioral signs of illness (e.g., Cornblatt, Lenzenweger, Dworkin, & Erlenmeyer-Kimling, 1992; Erlenmeyer-Kimling & Cornblatt, 1978, 1987). Subjects who later developed a Schizophrenia spectrum disorder consistently displayed a lower performance level on the continuous performance test (CPT), a measure of sustained and selective attention, relative to subjects in all comparison groups (unaffected children of parents with Schizophrenia, children of parents with affective disorder, and normal comparison subjects), and the magnitude of this deficit remained constant across development. Further, a measure of cognitive performance deviance at age 9 (composed largely of CPT performance measures) had high specificity and moderate sensitivity for predicting relatively serious behavioral disturbances (including social impairment and problems at school and at home) emerging in high-risk subjects during mid-adolescence (Cornblatt & Erlenmeyer-Kimling, 1985). These findings suggest that these early attentional deficits are associated with later emerging social difficulties in genetically at-risk individuals (Cornblatt et al., 1992).

Although high-risk studies have been instrumental in revealing a relationship between genetic liability to Schizophrenia and early forms of impairment, such findings may not be generalizable, given that only 5% to 10% of patients with Schizophrenia have a parent with Schizophrenia. Further, because offspring in most high-risk samples have not passed through the period of elevated risk for onset of Schizophrenia, and those that have include only a small number of participants who ultimately develop the disorder, there are limited data on the degree to which early deficits predict adult Schizophrenia in such samples. Thus, population-based cohorts are necessary to determine which precursors, or combination thereof, represent true risk factors for Schizophrenia. Using data from the 1946 British birth cohort, Jones, Rodgers, Murray, and Marmot (1994) found that individuals who were later diagnosed with Schizophrenia had lower educational test scores at ages 8, 11, and 15 than nonpsychiatric controls from the same cohort. Additionally, there was a linear trend of increased risk for Schizophrenia across decreasing levels of cognitive performance, which became stronger with age. In

a study of male conscripts from the 1969 to 1970 Swedish army cohort, David, Malmberg, Brandt, Allebeck, and Lewis (1997) demonstrated a similar linear relationship between IQ at age 18 and subsequent development of Schizophrenia, such that the risk for Schizophrenia increased as IQ decreased across the range of cognitive ability. In a Philadelphia birth cohort of approximately 10,000 subjects, T. D. Cannon, Huttunen, et al. (2000) found significant cognitive impairment in school-age individuals who later developed Schizophrenia. Moreover, there were significant linear trends in the distribution of IQ scores, indicating that preschizophrenic individuals were significantly over-represented in the lowest quintile of cognitive performance and increasingly under-represented among the upper quintiles.

There remains some question as to the developmental course of such early cognitive impairments in preschizophrenic individuals. Russell, Munro, Jones, Hemsley, and Murray (1997) examined change in IQ among individuals who presented to Maudsley Hospital as children and subsequently developed Schizophrenia as adults. Although the mean Full-Scale IQ (FSIQ) in this group was over 1 standard deviation below the scores of the general population, there was no evidence of a decline from child to adult IQ. The authors concluded that the deficit in intellectual function observed in Schizophrenia may be present in childhood and remain stable throughout this developmental period. In contrast to the findings of Russell et al., a study of Israeli military draftees found that draftees who eventually developed Schizophrenia showed a measurable decline in cognitive performance that began about 2 years prior to illness onset, concomitant with impaired social functioning that became progressively worse during the course of late adolescence (Davidson et al., 1999). Consistent with this finding, adolescent and young adult participants in the Edinburgh High Risk Study exhibited significantly lower premorbid IQ, as assessed by the National Adult Reading Test, and lower FSIQ on the Weschler Adult Intelligence Scale at baseline when compared to controls (Byrne, Hodges, Grant, Owens, & Johnstone, 1999). At 2-year follow-up, those high-risk participants who had experienced an increase in psychotic symptoms exhibited an apparent decline in IQ and memory (Cosway et al., 2000), suggesting that onset of psychosis may coincide with a decline in cognitive function.

There is considerable variation in the kind of early behavioral problems displayed by individuals who ultimately develop Schizophrenia. Retrospective and prospective cohort studies have consistently documented the existence of abnormalities in premorbid social development in preschiz-

ophrenic individuals, ranging from solitary play preference at age 4 to social anxiety, withdrawal, and acting-out behavior in adolescence (Jones et al., 1994). Preschizophrenic children are more likely than comparison children to be described by their teachers as “introverted,” “disagreeable” and “emotionally unstable” (Watt, 1978). Studies of childhood films have additionally revealed affective abnormalities in preschizophrenic children, with increases in negative facial expression as early as age 1 (Walker, Grimes, Davis, & Smith, 1993), suggesting that vulnerability to Schizophrenia may be associated more generally with “difficult” infant temperament (Walker, Lewine, & Neumann, 1996). In a prospective longitudinal study of a Philadelphia birth cohort, social maladjustment at age 7 was a significant predictor of adult Schizophrenia (Bearden et al., 2000). Rates of deviant behaviors (e.g., echolalia, meaningless laughter, and stereotyped behaviors) at ages 4 and 7 were significantly elevated in both preschizophrenic children and their unaffected siblings, suggesting that such problems may indicate genotypic susceptibility to the disorder and/or shared early environmental influences.

Interestingly, there is some evidence that childhood behavior problems among patients with Schizophrenia may provide clues regarding their ultimate illness presentation. For example, in the Copenhagen High-Risk Study, Cannon, Mednick, Parnas, et al. (1993) found different patterns of premorbid behavior among patients with predominantly negative or predominantly positive symptom Schizophrenia. Specifically, positive symptoms (i.e., hallucinations, delusions, thought disorder) were correlated with premorbid conduct disorder and acting-out behavior, and those patients with predominantly negative symptoms (i.e., apathy, anhedonia, social withdrawal) had more severe premorbid social maladjustment than those without such symptoms. Other studies have similarly documented poorer premorbid functioning and insidious onset with a predominantly negative symptom picture, providing support for the positive-negative symptom distinction in terms of natural history (McGlashan & Fenton, 1992; Pogue-Geile & Harrow, 1984).

Neurologic and motor abnormalities have also been identified in children vulnerable to Schizophrenia (Marcus, Auerbach, Wilkinson, & Burack, 1981; Mednick & Schulsinger, 1964). Fish (1977) found evidence of early neurological disturbance and delays in gross motor skills and visual-motor development in infant children of mothers with Schizophrenia. These infants tended to show unusually quiet behavior, including hypotonia, absence of crying, and underactivity. In a follow-up study, significant correlations were reported between the severity of neu-

rointegrative deficit and adult psychiatric status (Fish, 1987). Similarly, longitudinal follow-up of infants studied as part of the Jerusalem Infant Development Study revealed that the neurobehavioral deficits displayed in infancy by offspring of schizophrenic parents persisted over time, and the children who had developed Schizophrenia spectrum diagnoses by adolescence demonstrated poor neurobehavioral functioning across the developmental periods studied (Hans et al., 1999). A study of home movies obtained from families in which one child later developed Schizophrenia indicated that preschizophrenic children had significantly more neuromotor abnormalities and less developed motor skills than both their healthy siblings and individuals who later developed affective disorder (Walker, Savoie, & Davis, 1994). These findings have been confirmed in general population studies. In a Finnish birth cohort, early achievement of developmental milestones reduced the risk for psychotic disorder, whereas delayed milestones were predictive of psychosis (Isohanni et al., 2001). Additionally, two British cohort studies found that preschizophrenic children were retarded in their attainment of gross motor milestones during the first 2 years of life and were impaired on tests of motor coordination at 7 years of age (Crow, Done, & Sacker, 1995; Jones et al., 1994). Further, delayed motor development during infancy and impaired motor coordination during childhood have consistently discriminated between individuals at high and low genetic risk for Schizophrenia, indicating that early motor deviance may be a marker of genetic liability (Egan et al., 2001). Consistent with this interpretation, in the Philadelphia cohort of the National Collaborative Perinatal Project (NCPP), Rosso, Bearden, et al. (2000) found that deviance on motor coordination measures at age 7 was associated with both adult Schizophrenia and unaffected sibling status, suggesting that a cofamilial (and perhaps genetic) factor underlies motor coordination deficits in Schizophrenia. In addition, adolescents with schizotypal personality disorder have been reported to have elevated rates of involuntary movements of the head, trunk, and upper limbs as compared to nonill comparison subjects and adolescents with other personality disorders, further supporting the notion that certain motor abnormalities may reflect a genetic vulnerability to the disorder (Walker, Diforio, & Baum, 1999).

Several high-risk studies have found that the presence of multiple premorbid indicators, across domains of functioning, are associated with an elevated risk for Schizophrenia over and above single risk factors (Fish, 1987; Goodman, 1987; Marcus, Hans, Mednick, Schulsinger, & Michelsen, 1985). Consistent with this literature, findings from the

Philadelphia cohort of the NCPP showed that preschizophrenic children were more likely to exhibit multiple signs of impairment. This finding became increasingly pronounced over the course of development (T. D. Cannon, Rosso, Bearden, Sanchez, & Hadley, 1999). Evidence from the Dunedin, New Zealand, Health and Development Study further supports these findings, showing that persistent, multidimensional impairment in early childhood predicts psychotic symptoms in childhood and adulthood (M. Cannon et al., 2002). Whereas emotional problems and interpersonal difficulties were present in children who later developed psychotic, mood, or anxiety disorders, significant impairments in neuromotor, receptive language, and cognitive development were present only among children later diagnosed with schizophreniform disorder. This study also provides some of the first evidence of continuity of psychotic symptoms over the life span: Self-reported delusional beliefs and hallucinatory experiences at age 11 predicted a 16-fold increase in risk for schizophreniform disorder (but not mood disorder) at age 26 (Poulton et al., 2000). Such investigations are critical for the delineation of compelling risk factors that may increase positive predictive value in the identification of young people at risk for Schizophrenia.

Interestingly, there is emerging evidence suggesting that functional impairment during adolescence may have more predictive value in the identification of young people at high risk for Schizophrenia than that attained in studies of childhood functioning (Davidson et al., 1999). Because of this, epidemiologic studies of Schizophrenia risk have begun to move forward in the ontology of the illness, progressing from stages that clearly precede clinical signs of the disorder to those more proximal to the onset of psychosis (Cornblatt, Lencz, & Obuchowski, 2002).

THE CASE FOR INVOLVEMENT OF LATER NEURODEVELOPMENTAL PROCESSES IN SCHIZOPHRENIA

By definition, a substantial decline in role functioning and a severe disruption in integrated cognitive and emotional processing occurs around the time of onset of Schizophrenia during late adolescence and early adulthood. In view of this pattern, it is tempting to postulate that there are brain changes in addition to those instantiated through early neurodevelopmental influences that occur proximally to the onset of psychosis, thus acting as triggers for this functional

decline and psychotic symptom expression (see right section of Figure 14.1). As noted previously, the most well-established disease-related deficits in Schizophrenia involve frontal and temporal lobe structures, abnormalities of which have been linked to the occurrence of hypoxia-associated birth complications among individuals with Schizophrenia. Nevertheless, as we shall see, the hippocampus and surrounding temporal cortex are also among the regions that have been shown in some studies to deteriorate in the early course of Schizophrenia (Giedd et al., 1999). The question then becomes, if these disease-related deficits are present to some degree from early in life, what mechanisms cause them to further deteriorate in adolescence/early adulthood, and are these mechanisms primary or secondary to the emergence of psychosis?

Anatomical Changes in First-Episode Schizophrenia

Longitudinal prospective studies of patients during their first episode of psychosis can deepen our understanding of late processes underlying onset of Schizophrenia, as these patients have had minimal exposure to potential confounding factors, such as pharmacological agents and chronicity (Bagary et al., 2003). Moreover, there is evidence that structural brain changes associated with Schizophrenia are at their peak intensity during the initial stage of illness (Gur et al., 1998; Kasai et al., 2003). Several lines of evidence suggest that developmental anomalies associated with Schizophrenia may vary depending on the developmental stage of the individual at illness onset (Brewer et al., 2003; Mathalon, Rapoport, Davis, & Krystal, 2003; Mehler & Warnke, 2002). The National Institute of Mental Health (NIMH) study of childhood-onset Schizophrenia has been instrumental in shedding light on the ways in which age of onset may interact with normative developmental processes during early disease progression. Thompson et al. (2001) analyzed repeated high-resolution MRI brain scans of adolescent patients with childhood-onset Schizophrenia. The authors discovered a dynamic pattern of gray matter loss that began in the parietal region and progressed forward to the temporal and frontal cortices. The final pattern of loss was consistent with cross-sectional studies of adults with Schizophrenia, showing a relatively greater degree of reduction in frontal and temporal cortical volumes. Further reports from the NIMH study have revealed deviant patterns of development in the corpus callosum and the cerebellum among patients with childhood-onset Schizophrenia (Keller, Castellanos, et al.,

2003; Keller, Jeffries, et al., 2003). Notably, there appears to be diagnostic specificity to this pattern of progressive gray matter loss: For children and adolescents with transient psychotic symptoms that did not meet criteria for Schizophrenia, gray matter reduction over time did not differ from that observed in healthy comparison subjects (Gogtay et al., 2003). These patients provide a valuable comparison group to the childhood-onset Schizophrenia patients because they had a similar level of cognitive functioning and had received a similar course of treatment with antipsychotic medication, indicating that these brain changes are intrinsic to the illness and do not result from medication exposure. In addition, the unaffected siblings of these childhood-onset Schizophrenia patients were found to have smaller total brain volume and reduced total, frontal, and parietal gray matter volume as compared to healthy controls (Gogtay et al., 2003). When divided into younger and older age groups, the younger siblings (under 18 years old) had smaller parietal gray matter volumes than matched controls, and older siblings showed trends toward smaller total cerebral volume and smaller frontal gray matter volume. Although a longitudinal study is required to confirm the significance of this finding, it suggests that healthy siblings of childhood-onset Schizophrenia patients share neuroanatomic abnormalities that may follow a similar pattern of developmental progression.

Findings from longitudinal prospective studies of adult first-episode patients have been mixed. Some studies have revealed broad changes in whole-brain volume but no detectable progression in specific regions, such as the temporal or frontal lobe structures (Cahn et al., 2002; DeLisi et al., 1997; Pantelis, Yucel, Wood, McGorry, & Velakoulis, 2003). Other studies of adults have revealed patterns of change similar to those seen in patients with childhood-onset Schizophrenia but of a much smaller magnitude (Gur et al., 1998). One study of adolescents and adults with recent-onset Schizophrenia, which utilized high-resolution scanning and differentiated gray and white matter, showed progressive decreases in gray matter volume in the left superior temporal gyrus during the 1st year and a half following initial hospitalization, followed by a leveling off of cortical deterioration (Kasai et al., 2003). To better understand age-related differences in brain development, future studies should differentiate between patterns of change in adolescents and adults. The only longitudinal imaging study that has specifically focused on patients with adolescent-onset Schizophrenia failed to show a pattern of progressive reduction in gray matter volume (James, Javaloyes, James, & Smith, 2002), except in the posterior inferior vermis

among male participants (James, James, Smith, & Javaloyes, 2004). The authors speculated that their negative findings may have reflected a leveling off of gray matter loss in late adolescence, as was found in the NIMH study (Sporn et al., 2003). However, it is notable that this study included a very small patient sample ($n = 16$). Thus, replication is warranted to determine if the degree of progressive gray matter loss found in the NIMH study is specific to childhood-onset Schizophrenia, or if similar patterns will be seen among adolescent-onset patients as they go through the same period of development.

Several studies have begun to explore the association between structural brain changes and clinical presentation during the first 2 years of illness. Gur et al. (1998) found that reductions in frontal and temporal lobe volume were associated with less improvement in negative symptoms and hallucinations in first-episode adult patients, as well as greater improvement with regard to delusions, when controlling for medication dose and compliance. Similar results have been reported by Sporn and colleagues (2003) and DeLisi, Sakuma, Ge, and Kushner (1998). In discussing these findings, investigators have proposed that this inverse relationship may be reflective of a process by which diseased tissue is removed through "compensatory pruning" (Gur et al., 1998; Sporn et al., 2003). In other words, it may be that the brain's normative process of synaptic elimination results in the removal of deviant neural connections, thus leading to clinical improvement.

Recently, there has been a debate in the literature regarding the value of longitudinal MRI studies for understanding the developmental neurobiology of Schizophrenia (Mathalon et al., 2003; Weinberger & McClure, 2002). Weinberger and McClure have challenged the validity of such studies for several reasons. First, they argue that the rates of neurodegeneration that have been reported in the literature seem unreasonably high, such that "by the time a patient with Schizophrenia reached age 60, there would be little brain left" (p. 556). Mathalon et al. counter this argument by citing evidence that rates of decline in gray matter level off with age, thus preserving significant brain tissue. Weinberger and McClure also note that variation in measurement and analysis techniques within and across studies makes it difficult to interpret findings. In response, Mathalon et al. point out that "the general convergence of recent findings despite these myriad sources of variance supports the likelihood that progressive morphometric changes in Schizophrenia do occur" (p. 846). These authors concede that longitudinal MRI studies cannot illuminate the mechanisms underlying progressive structural

change, but they emphasize the importance of these findings in moving the field beyond a strict “early influences” neurodevelopmental model.

Neuropsychological Changes in First-Episode Schizophrenia

Neuropsychological studies have similarly revealed that age of onset is a source of heterogeneity among patients with first-episode psychosis. Specifically, findings generally suggest that earlier onset yields more significant impairment across domains of cognitive functioning (Basso, Nasrallah, Olson, & Bornstein, 1997; Collinson et al., 2003). For example, Basso et al. compared adolescent-onset and adult-onset patients with chronic Schizophrenia and showed that patients with adolescent onset performed significantly less well than did patients with adult-onset Schizophrenia, particularly on memory and executive function tasks. Pantelis and colleagues (Pantelis, Velakoulis, et al., 2003) hypothesized that brain functions that typically develop during the peak period of risk will be most impaired among patients with Schizophrenia. For example, this group of investigators showed that working memory, a skill that develops throughout adolescence and peaks at age 20 (Pantelis, Velakoulis, et al., 2003), was more compromised among individuals in their sample of adolescents and young adults with Schizophrenia than was set shifting, a cognitive function that purportedly emerges earlier in development.

Studies exploring the longitudinal course of cognitive functioning during the initial stages of Schizophrenia may provide clues to the pathophysiology of the disorder. Such investigations have revealed that, in general, adults with first-episode Schizophrenia are impaired across broad domains of cognitive functioning but do not exhibit significant deterioration in abilities during the initial stages of illness. On the other hand, some cognitive abilities appear to show moderate improvement during this same period (DeLisi et al., 1995; Gold, Arndt, Nopoulos, O’Leary, & Andreasen, 1999; Heydebrand et al., 2003; Hoff et al., 1999), possibly as a result of treatment with antipsychotic medication and/or acute symptom remission. The one longitudinal study of cognitive function in first-episode adolescent patients used a cross-sectional design comparing recent-onset and chronic adolescent patients (Kravariti, Morris, Rabe-Hesketh, Murray, & Frangou, 2003). Results showed that patients at all stages of illness exhibited deficits in broad domains of cognitive functioning, but there was no evidence that chronic patients were more impaired than those with recent onset. These findings suggest

a lack of progressive deterioration in cognitive function over the course of illness.

Investigations of the relation between cognitive functioning and clinical features during the initial stage of Schizophrenia have shown that improvement with regard to negative symptoms is associated with enhanced performance on tests of memory, verbal fluency, psychomotor speed, and executive function (Heydebrand et al., 2003), as well as Performance IQ (PIQ) and FSIQ (Gold et al., 1999).

Magnetic Resonance Spectroscopy Studies

Although direct measures of abnormal neuronal growth and degeneration processes are difficult to quantify in vivo, nuclear magnetic resonance spectroscopy (MRS) offers a method of assessing brain phospholipid and energy metabolism that corresponds to developmental neuronal changes. This methodology allows a noninvasive investigation of human brain development and is well suited to identifying abnormalities in synaptic pruning that may occur in adolescence (Pettegrew, Klunk, Panchalingam, McClure, & Stanley, 2000). Two MRS techniques that are currently utilized in Schizophrenia research are phosphorus magnetic resonance spectroscopy (^{31}P -MRS) and proton magnetic resonance spectroscopy (^1H -MRS). In vivo ^{31}P -MRS examines indirect indicators of cell membrane synthesis and degradation in addition to measures of energy metabolism (Ross & Michaelis, 1994). ^{31}P -MRS studies have identified alterations of membrane phospholipid metabolites in the frontal cortex of first-episode, neuroleptic-naïve Schizophrenia subjects, as compared to matched controls (Keshavan, Pettegrew, Panchalingam, & Kaplan, 1991; Pettegrew, Keshavan, Panchalingam, & Strychor, 1991; Williamson, Pelz, Merskey, & Morrison, 1991), suggesting decreased synthesis and increased breakdown of membrane phospholipids in recent-onset Schizophrenia patients. This pattern resembles an exaggerated form of the changes observed in normal aging (Pettegrew & Minshew, 1992). Such findings may reflect an increase in membrane phospholipid turnover, perhaps because of an accelerated synaptic pruning process during late childhood and early adolescence (Keshavan et al., 2003). Keshavan et al. (1991) also found this pattern in one case prior to onset, suggesting that this process may be causally related to the onset of the disorder.

To further address this neurodevelopmental perspective, Stanley et al. (1995) used ^{31}P -MRS to examine the dorsolateral prefrontal cortex (DLPFC) in 11 drug-naïve, 8 newly diagnosed and medicated, and 10 medicated and chronic patients with Schizophrenia. Results showed decreased phospholipid synthesis in all three groups, which implies

lower levels of cell membrane synthesis at all stages of the disorder. Additionally, there was an increased level of phospholipid breakdown in the drug-naïve group, suggesting that earlier stages of Schizophrenia may be characterized by increased breakdown of cell membranes. At the level of structural neuroanatomy, these metabolic changes may correspond to increased gray matter volume loss in the early stages of illness. Abnormalities in phospholipid metabolism have also been observed in the DLPFC of high-risk adolescents (Keshavan, Stanley, Montrose, Minshew, & Pettegrew, 2003; Klemm et al., 2001; Rzanny et al., 2003). Such findings of aberrant phospholipid metabolism suggest a pattern of increased membrane turnover at illness onset with a continued pattern of membrane abnormalities throughout the course of the disorder (Berger et al., 2002).

¹H-MRS also provides indirect measures of metabolites related to neuronal and glial energy metabolism as well as phospholipid metabolism (Ross & Michaelis, 1994). Of the metabolites examined in ¹H-MRS, *N*-Acetylaspartate (NAA) is primarily seen as a marker of neuronal integrity (Keshavan, Stanley, & Pettegrew, 2000) that can be used to identify neurons and their dendritic and axonal extensions and is mostly concentrated in pyramidal neurons. NAA increases during the course of normal development until the adolescent period, when there is a decrease associated with pruning of superfluous neuronal connections. This is less drastic than the sharp decrease in NAA that is seen in neurodegenerative diseases (Moore, Slovis, & Chugani, 1998). Choline includes metabolites that are involved in the synthesis of myelin and cell membrane metabolism (Ross & Michaelis, 1994), and creatine (Cr) is defined as a general marker of energy metabolism (Passe, Charles, Rajagopalan, & Krishnan, 1995). The observation of decreased levels of NAA or a decreased NAA:Cr ratio is believed to indicate some form of neuronal loss, such as synaptic pruning or neuronal dysfunction, whereas increased levels of choline or an increased choline:Cr ratio signals deafferentiation (Ross & Michaelis, 1994). Glutamine is primarily found in glial cells; decreased levels of this metabolite are thought to represent neuronal loss, dysfunction, or deafferentiation (Ross & Michaelis, 1994).

Studies of ¹H-MRS in Schizophrenia have consistently reported reduced NAA levels in the hippocampus, mesial temporal lobe, and frontal lobe, including the DLPFC, in both adult- (Bertolino & Weinberger, 1999; Steel et al., 2001) and child-onset schizophrenic patients (Bertolino et al., 1998). Significant reductions in NAA:Cr ratios have been found in these regions in both chronic Schizophrenia patients (Bertolino et al., 1996; Yamasue et al., 2002; Yurgelun-Todd et al., 1996) and neuroleptic-naïve first-

episode patients (Cecil et al., 1998), as well as children with Schizophrenia spectrum disorders (Brooks et al., 1998). Supporting the idea that NAA:Cr ratio may mark genetic vulnerability to Schizophrenia, Callicott et al. (1998) showed a decreased NAA:Cr ratio in the hippocampi of both schizophrenic patients and their unaffected siblings when compared to healthy controls. Moreover, Keshavan and colleagues (1997) found that offspring of parents with Schizophrenia showed a reduced NAA:choline ratio in the anterior cingulate region when compared to healthy controls. Recent studies of neuroleptic-naïve patients with Schizophrenia (Bartha et al., 1997; Theberge et al., 2002) and offspring of parents with Schizophrenia (Tibbo, Hanstock, Valiakalayil, & Allen, 2004) have also revealed increased glutamate/glutamine levels in the medial frontal cortex, anterior cingulate, and thalamus, signaling possible dysfunction of glutamate in the pathogenesis of Schizophrenia.

Thus, although these studies demonstrate that altered NAA levels in frontal and temporal regions are associated with risk for Schizophrenia, it is not yet clear how anomalies in brain metabolites highlighted by MRS techniques correspond to brain volumetric changes and abnormalities of cellular migration in Schizophrenia. Some researchers have suggested that findings of decreased frontal NAA ratios may be related to effects of long-term antipsychotic treatment (Bustillo et al., 2001, 2002). Future refinements in MRS methodology offer the promise of more detailed exploration of neurogenesis and the processes of myelination, synaptic pruning, and gliosis.

The Schizophrenia Prodrome

With the shift in focus from a neurodevelopmental model of Schizophrenia to increasing interest in more proximal developmental risk factors, a new research strategy has emerged. Building on traditional high-risk approaches, the so-called ultra-high-risk (UHR) paradigm (Yung & McGorry, 1996; Yung et al., 1998) goes beyond indicators of genetic vulnerability to focus on clinical features that are believed to reflect heightened vulnerability for psychosis. A central goal in UHR research is to prospectively follow a well-characterized group of putatively prodromal individuals through the period of conversion to gain a deeper understanding of the progression of clinical, biological, and neurocognitive changes that characterize the onset of psychosis (T. D. Cannon et al., 2003; Meyer et al., 2005). Such studies may enhance our understanding of the pathophysiology of psychotic illness and allow for the discrimination of the Schizophrenia prodrome from that of other

conditions (e.g., affective psychosis), thus informing early treatment strategies (Phillips, Yung, Yuen, Pantelis, & McGorry, 2002). Finally, results of UHR research may aid in identifying late risk factors for the transition into psychosis, as well as protective factors or interventions that may alleviate, delay, or possibly prevent the onset of psychotic illness (T. D. Cannon et al., 2003; Yung et al., 2003).

Developmentally, the prodrome can be viewed as the transition between the premorbid and psychotic stages of illness (Cornblatt et al., 2002; Yung & McGorry, 1996). The first signal of deterioration occurs within 3 to 5 years of onset and consists of a constellation of gradually developing, low-grade psychiatric symptoms and signs, including reduced concentration (attention), decreased drive and motivation (anergia), depressed mood, sleep disturbance, anxiety, social withdrawal, suspiciousness, deterioration in role functioning, and irritability. Because these symptoms and signs are nonspecific—they also appear in primary affective and anxiety states—we refer to this initial period as the “predifferentiation” phase. The predifferentiation phase is typically followed, within about 1 year of onset, by the emergence of subpsychotic disturbances of thought and perception, including paranoid ideation, ideas of reference, unusual beliefs/magical thinking, perceptual disturbances (e.g., depersonalization, derealization), changes in thought and speech patterns, and atypical behavior and/or appearance. As these features represent attenuated forms of the cardinal symptoms and signs of psychosis, we refer to this period as the “differentiation” phase. The differentiation phase is often followed, within a few months of onset, by the emergence of transient psychotic symptoms, including hallucinations, delusions, and/or disorganized speech, which subside spontaneously within a period of a few hours to several days. We refer to this period of brief intermittent psychotic symptoms as the “micropsychotic” phase. The micropsychotic phase is considered to have evolved into full-blown Schizophrenia when prodromal behavioral features have been present continuously for at least 6 months and psychotic symptoms have persisted continuously for at least 1 month (American Psychiatric Association, 1994).

Over the past decade, investigators have identified three putatively prodromal syndromes that map onto the developmental sequence described. Criteria for these syndromes currently focus on three groups of individuals: (1) those who are experiencing attenuated positive psychotic symptoms that have emerged or worsened in the past year, (2) those who describe brief and intermittent periods of frank psychotic symptoms with recent onset, and (3) those with familial risk for a psychotic disorder and who have experi-

enced a significant decline in functioning in the past year. Operational definitions for these syndromes differ slightly across research programs. Table 14.1 presents the most widely used criteria for diagnosing the three prodromal states: the Criteria of Prodromal Syndromes (COPS; T. J. Miller et al., 2003) and the Comprehensive Assessment of At-Risk Mental States (CAARMS; Yung et al., 2003).

Although attempts to define the prodrome prospectively in clinical samples are relatively recent, initial evidence indicates that 22% to 54% of treatment-seeking individuals ascertained in a putatively prodromal state will convert to full-blown psychotic disorder within 2 years (McGlashan, Miller, & Woods, 2001; McGorry, Yung, & Phillips, 2003; Yung & McGorry, 1996; Yung et al., 1998). Thus, these studies offer the unique opportunity to identify behavioral and neurobiological markers most predictive of Schizophrenia outcome and, by extension, to develop interventions that may be implemented prior to onset of the full-blown disorder.

Results thus far have identified several baseline clinical variables that appear to be predictive of conversion to psychosis over and above prodromal criteria alone. Specifically, findings from the Melbourne Prodromal Study (Yung et al., 2003) suggest that poor functioning, as indicated by the following, was predictive of conversion to psychosis in their prodromal sample: a global assessment of functioning (GAF) score less than 51; prolonged duration of untreated prodromal symptoms (>900 days); high overall level of psychopathology, as measured by a total score on the Brief Psychiatric Rating Scale (BPRS) greater than 15; sub-threshold psychotic symptoms, as measured by a BPRS psychotic subscale score greater than 2; depression, as measured by a Hamilton score greater than 18; and clinically significant avolition and anxiety. Strikingly, 87% of those participants who had four or more of these risk factors converted to psychosis within 6 months after study entry.

Investigators have also begun to explore neuropsychological and structural brain changes associated with conversion to psychosis. Early results from the Melbourne UHR study suggest that none of the neuropsychological variables that were assessed at baseline successfully distinguished between those UHR patients who converted to psychosis and those who did not (Wood et al., 2003). Investigators from this study examined tasks of spatial working memory and delayed matching-to-sample in 38 young people at ultra high-risk of developing psychosis (of whom nine later became psychotic), as compared to 49 healthy controls. Performance on both tasks was significantly poorer in the UHR group overall. Those who later became psychotic generally performed more poorly than

TABLE 14.1 Criteria for the Three Prodromal Syndromes as Defined by the Criteria of Prodromal Syndromes (COPS) and the Comprehensive Assessment of At-Risk Mental States (CAARMS)

		Criteria of Prodromal Syndromes (COPS; T. Miller et al., 2003)	Comprehensive Assessment of At-Risk Mental States (CAARMS; Yung et al., 2003)
Group 1	Attenuated Positive Symptom Syndrome	At least one of the following five scales is scored within the attenuated range: 1. Unusual thought content/delusional ideas. 2. Suspiciousness/persecutory ideas. 3. Grandiosity. 4. Perceptual abnormalities/hallucinations. 5. Disorganized communication. Symptoms began within the past year or have intensified within the past year. Symptoms have occurred at least once per week for the past month.	At least one of the following symptoms is scored within the attenuated range and held with a reasonable degree of conviction, as defined by a score of 2 on the Comprehensive Assessment of Symptoms and History (CASH; Andreasen et al., 1992): 1. Ideas of reference. 2. Odd beliefs or magical thinking. 3. Perceptual disturbance. 4. Paranoid ideation. 5. Off thinking and speech. 6. Odd behavior and appearance. Symptoms have been present for at least 1 week and no longer than 5 years. Symptoms occur at least several times per week.
Group 2	Brief Intermittent Psychotic Symptoms Syndrome (SIPS) OR Brief Limited Intermittent Psychotic Symptoms (CAARMS)	One or more of the above five scales is scored within the psychotic range. Symptoms began in the past 3 months. Symptoms presently occur for at least several minutes per day at least once per month.	Transient positive psychotic symptoms last less than a week. Symptoms resolve spontaneously. Onset is within the past year.
Group 3	Genetic Risk and Deterioration Syndrome (SIPS) OR Trait and State Risk Factors (CAARMS)	Participant has a first-degree relative with a history of any psychotic disorder. OR Participant meets criteria for Schizotypal Personality Disorder. Participant has experienced a 30% drop in global assessment of functioning (GAF) from premorbid level. Change in GAF has lasted for at least a month.	Participant has a first-degree relative with a psychotic disorder or Schizotypal Personality Disorder. OR Participant meets criteria for Schizotypal Personality Disorder. Participant has experienced a 30-point drop in GAF from premorbid level. Change in mental status or functioning has lasted for at least a month. Onset is within the past year.

those who did not, but this difference did not reach statistical significance. A significant correlation between spatial working memory errors and negative symptoms was seen in the later-psychotic group only, suggesting that this may be a useful predictive factor to examine in future studies. Additionally, in a larger group of UHR participants, these investigators found significantly impaired olfactory identification ability in those who later developed a Schizophrenia spectrum disorder, but not in any other group, suggesting that impaired olfactory identification may be a premorbid marker of transition to Schizophrenia (Brewer et al., 2003). Replication is warranted to determine whether this finding may be generalizable to other prodromal samples.

With regard to structural anatomic risk factors, Pantelis and colleagues (Pantelis, Velakoulis, et al., 2003) reported striking baseline differences in regional gray

matter volume between those participants who subsequently developed a psychotic illness and those who did not. Specifically, those who developed psychosis had less gray matter in the right medial temporal, lateral temporal, and inferior frontal cortex, and in the cingulate cortex bilaterally. Longitudinal follow-up indicated that individuals who developed psychosis showed a postmorbid reduction in gray matter in the left parahippocampal, fusiform, orbitofrontal and cerebellar cortices, and the cingulate gyri, whereas longitudinal changes were restricted to the cerebellum in those who did not become psychotic. Interestingly, contrary to expectation, *larger* left hippocampal volume at intake was associated with the subsequent development of acute psychosis, rather than smaller volumes (Phillips, Velakoulis, et al., 2002). These results appear to be at odds with the genetic high-risk studies described earlier and highlight the importance of

different ascertainment strategies in terms of defining risk, as well as the need for more longitudinal research on prodromal subjects who are both genetically at risk for psychosis and exhibiting early symptoms.

The Role of Stressful Life Events and Their Neurobiological Effects

We have described the role of prenatal stress as an early occurring factor and now turn our attention to the potential moderating role of psychosocial stress as a late factor in adolescence and adulthood (see right section of Figure 14.1). Diathesis-stress models of Schizophrenia suggest that environmental stress may interact with genetic vulnerability in triggering the onset of psychotic symptoms and exacerbating symptoms during the course of the disorder. A 1985 review of the behavioral literature regarding the role of psychosocial stress in Schizophrenia concluded that evidence for a causal role was weak, though some findings pointed to a potential role of stress in activating symptoms in previously diagnosed psychotic patients (Tennant, 1985). Additional research since that time has continued to support these conclusions, with the addition of a more complex understanding of the neurobiological effects of stress on the central nervous system.

Several studies have examined the temporal relationship between stressful life events and symptom severity, pointing to a role for environmental stressors in psychotic symptom exacerbation and relapse. In a landmark study, retrospective assessments indicated that independent life events (those life events judged *not* to be due to the mental illness) were more likely to occur in the 3 weeks prior to onset of a psychotic episode in Schizophrenia patients than in a similar period of time for nonpsychiatric control participants (Brown & Birley, 1968). This sample included first-episode and more chronic patients, all of whom had a rapid increase in symptoms prior to episode onset. The authors calculated that onset was “brought forward” by 10 weeks, on average, for these patients, thus providing the first evidence for the “triggering hypothesis” (Birley & Brown, 1970; Brown & Birley, 1968). This theory proposes that an underlying biological vulnerability causes psychosis, and environmental stress may trigger the precise timing of onset. In an early study by Leff, Hirsch, Gajnd, Rohde, and Stevens (1973), in the 5 weeks preceding psychotic relapse, patients with Schizophrenia maintained on antipsychotic medications were more likely to experience an independent life event (89% of patients) than both well patients taking antipsychotic medications (27%) and well or relapsed pa-

tients taking a placebo (38% and 31%, respectively). However, other studies failed to replicate the increase in independent events prior to episode onset (Jacobs & Myers, 1976), and the theory cannot be said to generalize to patients with a gradual onset of psychotic symptoms.

In a review of the behavioral literature on stress and Schizophrenia, Norman and Malla (1993) examined 23 studies that retrospectively assessed life events prior to psychotic onset or relapse (only three assessed first-episode patients) and reported that 77% of the studies showed significant evidence that higher stress levels were associated with more severe symptoms in schizophrenic samples. Thirty-six percent of the comparisons between Schizophrenia patients and nonpsychiatric controls showed higher rates of independent events in the lives of patients, and none of the studies that compared Schizophrenia patients to control subjects with other psychiatric disorders showed higher rates of life events for the Schizophrenia patients compared to patients with other psychiatric disorders (Norman & Malla, 1993). Although the measurement of independent events attempts to control for the effect of illness in creating life stress, the direction of causality is not yet clear: Life events could exacerbate symptoms, and increased symptoms could increase the level of stressful events in a patient's life. Additionally, psychosocial stress may not have a unique effect on psychotic symptoms, as life events have also been linked to an increase in mood symptoms in patients with Schizophrenia (Ventura, Nuechterlein, Subotnik, Hardesty, & Mintz, 2000) and patients with purely affective disorders (Brown & Harris, 1978). Life stress is thought to exacerbate psychiatric symptoms across a variety of mental disorders and may also exacerbate immune system functioning and the symptoms of physical illness in diseases such as diabetes, cardiovascular disease, and cancers (S. Cohen & Herbert, 1996; Spiegel & Kato, 1996; Strike & Steptoe, 2004).

High-risk paradigms are just beginning to examine the link between stress and symptoms. Among genetically high-risk participants who did not qualify for a psychotic disorder diagnosis, the number of lifetime major life events were related to psychotic symptom severity (P. Miller et al., 2001). However, these subjects have not yet been followed through the period of risk for conversion to psychosis. No prospective studies of stressful life events prior to illness onset have been completed, although they are the best test of the stress-vulnerability hypothesis because they reduce recall bias. Corcoran and colleagues (2003) proposed a model for examining the effects of stress on symptom onset for clinically at-risk (prodromal) groups, in

which both life events and neurobiological assays can be used to measure stress and patients' stress response. This design would allow researchers to directly examine potential candidate biological mechanisms that may link stress to symptoms.

A hypothetical neurochemical mechanism linking the stress system to symptoms of Schizophrenia is altered activity of the hypothalamic-pituitary-adrenal (HPA) axis. The cascade of hormones in response to stress proceeds through the HPA pathway as cells in the paraventricular nucleus of the hypothalamus secrete corticotropin-releasing hormone, which increases adrenocorticotrophic hormone secretion by the pituitary gland, which stimulates the adrenal gland to release glucocorticoids, which then feed back via glucocorticoid receptors in the hippocampus to dampen the system once the stressor has passed (Figure 14.2).

Figure 14.2 The hypothalamic-pituitary-adrenal (HPA) axis. The HPA axis activates in response to stress and is inhibited via a negative feedback loop. Reproduced with permission from Sinauer Associates. Rosenzweig et al., 1999, *Biological Psychology*, 3rd ed.

Elevated levels of cortisol may exacerbate symptoms through a neurotoxic effect on the hippocampus (McEwen & Seeman, 1999) and by ultimately increasing dopaminergic activity in the prefrontal cortex (Walker & Diforio, 1997). In animal models, prolonged stress has been shown to result in a dysregulated negative feedback circuit, whereby damaged hippocampi fail to correctly modulate HPA axis activity (Sapolsky, Uno, Rebert, & Finch, 1990). On the basis of animal models, some have argued that stress also increases glutamate in both the prefrontal cortex (PFC) and the hippocampus, which can result in altered dopamine levels (Moghaddam, 2002). The increase in PFC glutamate, as opposed to the hippocampus, does not appear to be dependent on glucocorticoids, and therefore may represent a second pathway that is activated as part of the brain's "fast response" to stress, which occurs prior to and during the stress response via the HPA axis (Lowy, Gault, & Yamamoto, 1993; Moghaddam, Bolinao, Stein-Behrens, & Sapolsky, 1994). Although a review of basic research on stress in animal models as related to Schizophrenia is outside the scope of this chapter (see Corcoran et al., 2003, for a review), this type of research has vastly increased our understanding of the body's complex stress response and its effects on the mind and brain.

Studies of patients with Schizophrenia have primarily utilized cortisol assays to assess HPA axis integrity. Walder, Walker, and Lewine (2000) reported that salivary cortisol levels were related to symptom severity in a sample of patients with Schizophrenia, as well as performance on neuropsychological tasks in a combined sample of patients with Schizophrenia, affective disorder, or no history of psychiatric illness. Kaneda, Fujii, and Ohmori (2002) found that patients with Schizophrenia showed heightened baseline plasma corticotropin (ACTH) levels, in addition to elevated cortisol levels in response to physical stressors in a research setting (Jansen, Gispen-de Wied, & Kahn, 2000). In contrast, other studies have shown that patients with Schizophrenia show a dampened cortisol response to psychosocial stress such as public speaking (Jansen et al., 1998, 2000). Differences in findings across studies may reflect variation in research procedures such as the collection of assays (plasma versus salivary cortisol) and the timing of tests, as circadian rhythms greatly affect stress hormone levels (Kirschbaum & Hellhammer, 1989).

Although no studies of HPA axis functioning in the pre-morbid or prodromal periods of Schizophrenia have been published to date, one study has focused on adolescents with schizotypal personality disorder (SPD). Individuals diagnosed with SPD are at higher risk for developing Axis I

psychotic disorders and may possess a similar genetic vulnerability to Schizophrenia (Fenton & McGlashan, 1989; Siever, Kalus, & Keefe, 1993). Adolescents with SPD were found to have higher levels of salivary cortisol than adolescents with other personality disorders and normal controls, especially at the first sample of the day (Weinstein, Diforio, Schiffman, Walker, & Bonsall, 1999). In a longitudinal follow-up, cortisol levels at baseline and follow-up assessments were correlated with schizotypal symptoms at the second assessment, pointing to a potential relationship between HPA axis functioning and the development of psychiatric symptoms in psychosis, although this study has not yet followed the participants through the complete period of risk for onset of psychotic disorders (Walker, Walder, & Reynolds, 2001). Longitudinal studies can also help to determine the long-term effects of chronic stress on HPA axis functioning in Schizophrenia.

Genetic and Hormonal Regulation of Synaptic Pruning

In addition to the role of hormones in mediating stress response, hormones are likely to play a key role in adolescent brain maturation (Walker & Bollini, 2002). Gonadal and adrenal hormones have been shown to affect structural development, as well as immediate functional properties, of the brain. Some of the behavioral influences exerted by these hormones are short-term “nongenomic” effects, mediated by receptors on the surface of neurons; steroid hormones also affect later gene expression via intracellular hormonal receptors in neurons (McEwen, 1994; Watson & Gametchu, 1999). Animal research has demonstrated that hormones can trigger gene expression relevant to postpubertal neuromaturation processes (Ojeda & Ma, 1999). For example, estrogen-induced cyclic synaptogenesis has been observed in the adult rat hippocampus (McEwen, 1994). These genomic effects of hormones involve changes in the expression of messenger RNA that codes for specific proteins that, in turn, play a role in receptor density, reuptake, and neurotransmitter synthesis. These proteins can also trigger the expression of genes that impact neuronal survival (govern maturational processes such as proliferation and elimination of neurons). Thus, structural plasticity is an important aspect of steroid hormone action in the developing nervous system (McEwen, 1994). The role of genomic hormonal effects in triggering onset of Schizophrenia is purely speculative, but some investigators have hypothesized that hormonal changes during adolescence, especially of the reproductive steroids, may trigger the expression of faulty genes, possibly affecting

synaptic pruning and/or myelination (Amateau & McCarthy, 2002). This is supported by observations that age-related gray matter volume reductions during adolescence in healthy males might be steeper than those of healthy females (DeBellis et al., 2001). One mechanism by which rising hormone levels in adolescence may trigger expression of a latent genetic predisposition to Schizophrenia is through dysregulation of the HPA axis. It is also possible that early hippocampal insult (i.e., due to prenatal complications) may increase the likelihood that a latent genetic predisposition to Schizophrenia will be expressed in adolescence (Walker & Bollini, 2002). Thus, early environmental insult may alter gonadal hormone expression; alternatively, effects of hormones may alter the nature of the early insult (Andersen, 2003).

Interactions between Early and Late Risk Factors

Theories regarding the development of psychotic symptomatology in the adolescent period must also account for findings of early childhood abnormalities in patients with Schizophrenia (Walker & Bollini, 2002). Keshavan and colleagues (Keshavan, 1999; Keshavan & Hogarty, 1999) have proposed that Schizophrenia arises from both an early brain abnormality and late maturational processes of brain development interacting with adverse biochemical and psychosocial factors during adolescence and early adulthood. That is, prenatal and/or early postnatal factors (genetic or environmental) produce anomalous neural connectivity, resulting in premorbid impairment. Subsequently, during adolescence, the onset of prodromal or fully psychotic symptoms may result from excessive elimination of synapses and, secondarily, phasic dopaminergic overactivity. Because normal ingrowth of dopamine fibers occurs during the late adolescent period (Benes, 1997), other investigators have hypothesized that developmental changes in dopamine levels may drive the onset of positive symptoms of Schizophrenia at that time, thereby moderating the expression of congenital neuropathology in vulnerable individuals (Walker et al., 1994; Weinberger, 1995).

Such a progressive developmental pathophysiology of the illness during adolescence (Woods, Grafton, Holmes, Cherry, & Mazziotta, 1998) may result from several factors working singly or in combination. First, genetic factors may predispose to an excess synaptic elimination, increased neuronal apoptosis (i.e., programmed cell death), decreased cell somal size, or a combination of these processes during adolescence. Such changes might result from altered expression of genes that are critical for neurodevelopmental processes (Nawa, Takahashi, & Pat-

terson, 2000; Olney & Farber, 1995) or altered dynamics of dopaminergic and GABAergic neurotransmitter systems (Costa et al., 2001). Second, hormonal changes, especially of the reproductive steroids, could modulate brain maturational processes such as synaptic pruning and/or myelination (Amateau & McCarthy, 2002). Third, psychosocial environmental factors might play a significant role. It is known that environmental enrichment leads to increased spine density and dendritic arborization (Globus, Rosenzweig, Bennett, & Diamond, 1973). Likewise, environmental impoverishment or stress could conceivably lead to the opposite, that is, an increased fall-out of synapses and/or neurons (Teicher, Andersen, Polcari, Anderson, & Navalta, 2002) and decreased neuronal viability (DeBellis et al., 2001).

Findings linking gray matter reductions and other gross morphological changes in Schizophrenia to fetal hypoxia (T. D. Cannon, van Erp, Rosso, et al., 2002) suggest a specific mechanism by which such early influences interact with later maturational changes in influencing the timing of onset of the disorder. Of particular importance, fetal hypoxia is consistently associated with earlier onset forms of the disorder (Bearden et al., 2000; Rosso, Cannon, et al., 2000; Verdoux et al., 1997), suggesting that the presence of this risk factor may in some manner predispose to an earlier age at onset. The neural sequelae of hypoxia vary in severity from alterations in neurite outgrowth to neuronal cell death (Nyakas et al., 1996). In the former case, immature neurons may survive the hypoxic insult but still have a compromised elaboration of synaptic interconnections (Nyakas et al., 1996). Studies in fetal sheep have shown that hypoxia secondary to chronic placental insufficiency is associated with reduced cortical thickness and increased cortical neuronal density, without any observable neuronal loss (Rees et al., 1998). The pattern of morphologic changes associated with hypoxia in studies of Schizophrenia is thus compatible with an animal model of chronic fetal hypoxia and with the observed cellular pathology in schizophrenic patients. In this context, processes associated with cortical synaptic pruning during late adolescence and early adulthood (Feinberg, 1982; Keshavan, Anderson, & Pettegrew, 1994) might interact with the earlier hypoxia-related effects in lowering interneuronal connectivity to below a threshold critical for integrated cognitive activity, leading to further behavioral deterioration at that time.

Thus, current models offer promising hypotheses regarding mechanisms by which processes associated with postpubertal brain development might interact with earlier compromises of the brain in predisposing to Schizophrenia. Nevertheless, theories as to why adolescence represents a

time of increased risk for Schizophrenia onset remain speculative. It may be that heterogeneity in the course and outcome of Schizophrenia is a function of the interaction of early brain pathology with normal or abnormal developmental factors occurring throughout life, up until the time when the illness commences (Pantelis, Yucel, et al., 2003). The role of later environmental stressors, and how they may impact an already vulnerable individual, warrants further investigation in naturalistic human studies and via experimental animal models.

SUMMARY AND CONCLUSIONS

According to the original neurodevelopmental hypothesis of Schizophrenia, the disorder results from a set of basic biological errors that occur early in life and lead to a combination of structural, functional, and/or biochemical anomalies in the developing brain (T. D. Cannon & Mednick, 1993). This model of Schizophrenia has been highly influential and has moved the field substantially forward by focusing attention on early developmental deviation in individuals who develop the illness in adulthood. Specifically, in the area of epidemiology, this model has led to the investigation of early signs of functional compromise in individuals destined to develop Schizophrenia in adulthood, and the interaction of specific obstetric complications with genetic factors in the etiology of psychotic illness. Convergent evidence from neuropathological investigations indicates patterns of neuronal displacement consistent with a neurodevelopmental origin.

However, a major limitation of this model is that it does not account for the delay in onset of the disorder. Why does full-blown Schizophrenia typically manifest during the late adolescent/early adult period? Taken together with recent evidence of neuroanatomic change during the early phase of illness, it seems likely that additional factors active during this period play a role in the disease process.

Recent advances in our understanding of processes that occur proximal to illness onset call for an update to the neurodevelopmental model. It is important to keep in mind that progressive anatomic changes do not preclude the existence of a neurodevelopmental insult in Schizophrenia, as an inherited neurodevelopmental abnormality may also have progressive features (Mathalon et al., 2003). Here we have outlined a model in which some neurocognitive and neuroanatomic abnormalities reflect genetic trait markers, others are environmentally mediated, and the development of frank psychosis may involve a third, partially overlapping series of structural and functional changes. Theorists

have focused on two sources of influence that might account for neuronal disruption proximal to the time of onset of illness: pruning-related plasticity processes that occur as a normative aspect of brain development during adolescence, and stress-related and other hormonal changes that may have neurotoxic effects in pathways implicated in the pathophysiology of Schizophrenia. In regard to the former, certain Schizophrenia-related factors may disrupt the regulation of regressive brain maturational events at this time. Such a model is supported by evidence of a Schizophrenia-promoting variant in a plasticity-related gene (*DISC1*) associated with prefrontal cortical gray matter reduction. However, it is also possible that there is nothing intrinsically wrong with these later maturational brain processes in individuals predisposed to Schizophrenia, but these processes nevertheless participate in determining the timing of onset of functional deterioration and psychotic symptom formation by reducing the reserve of interneuronal connectivity to below some hypothetically critical threshold (Hoffman & McGlashan, 1997).

Clearly, the question of whether brain abnormalities in Schizophrenia are static or dynamic is one that is critical for future research to resolve. If the primary pathologic condition in Schizophrenia indeed reflects anomalous processes that occur early in development (e.g., Murray & Lewis, 1987; Weinberger, 1987), it has yet to be resolved whether such an abnormality signifies a failure of normal development due to a fixed early insult, a failure in an ongoing maturational process such as synaptic pruning, a degenerative process from a stage achieved through normal development, or some combination of these factors (T. D. Cannon et al., 2003). A deeper understanding of normal neurodevelopmental events is clearly critical for elucidating the potentially abnormal pathophysiological processes at work in Schizophrenia.

Increasingly sophisticated methodologies such as high-resolution MRI and MRS currently offer researchers the possibility of investigating these neurobiological processes. However, it is not yet known whether such brain metabolic alterations are causally relevant to onset or merely epiphenomena of other neurodevelopmental processes at work. In this regard, the functional significance of volumetric reduction noted in longitudinal MRI studies is a paramount question. As such changes do not appear to be accompanied by neurodegenerative processes at the cellular level, it is possible they may reflect short-term physiological variability or plasticity that does not signify ongoing deterioration.

A second, related issue is the differentiation of risk factors that are causal and could thus represent potentially im-

portant therapeutic targets, as compared to markers of vulnerability that may identify those at greatest risk but do not necessarily or directly impact the later course of illness. The identification of causal risk factors, such as particular neurocognitive deficits or brain abnormalities, has obvious implications both for research and for the development of new treatments that may improve the quality of life for individuals suffering from the disorder and is thus a primary goal of current clinical high-risk research.

From a developmental perspective, the unfolding of the clinical disorder is a long-term process, involving multiple developmental phases, different types of risk factors, and the understanding that psychosis is in no way an inevitable outcome (Cornblatt et al., 2002). A better understanding of the developmental trajectory of neurobiological processes in Schizophrenia will inform early intervention strategies as to the most vulnerable brain functions and/or structures, as well as the stages of the illness most amenable to treatment (Pantelis, Yucel, et al., 2003). Such intervention strategies offer promise that the functional deterioration related to onset of the clinical disorder may be delayed, attenuated, or ultimately prevented altogether.

FUTURE DIRECTIONS

There are several critical avenues for future research, which are currently in the early stages, but show great promise for both advancing our understanding of the pathophysiology of Schizophrenia, and improving outcomes for individuals who suffer from the illness. These include: (1) advances in early identification and intervention for at-risk individuals, (2) identification of neural endophenotypes, which are likely to be closer to the underlying genetic etiology of the disease, and (3) utilizing these more discrete, quantifiable definitions of pathological phenotypes in order to improve treatment and interventions for Schizophrenia.

Advances in Early Intervention

It is clear from the literature summarized here that the first few years of psychosis represent a critical period in that many patients show substantial cognitive and social deterioration, which has extremely detrimental effects on long-term success in functioning independently (Hafner & Nowotny, 1995; Yung & McGorry, 1996). Nevertheless, because current mental health care practices are largely reactive rather than proactive in nature, and because the public is poorly educated about the nature and early signs of men-

tal illness, there is often a substantial delay before young people with onset of psychotic symptoms are evaluated and treated psychiatrically (Johnstone, Crow, Johnson, & MacMillan, 1986; Loebel et al., 1992). Antipsychotic drug therapy is effective in producing partial symptom relief in many patients, but it is not curative (Glick, Suppes, DeBattista, Hu, & Marder, 2001; Marder, 1996). Findings indicating poorer treatment response and functional impairment given longer duration of untreated psychosis (e.g., Crow, MacMillan, Johnson, & Johnstone, 1986; Loebel et al., 1992) argue for a new approach to ascertain at-risk individuals before the onset of Schizophrenia and to provide interventions designed to stave off illness progression and to improve functioning and long-term outcome.

A better understanding of the neurodevelopmental trajectory in high-risk individuals who develop Schizophrenia, as compared to those who do not, will advance our knowledge regarding aspects of brain structure and function that may improve the prediction of onset of Schizophrenia over and above that associated with behavioral prodromal features and family history. Such studies will also elucidate the temporal and spatial pattern of neural and behavioral changes associated with the emergence of prodromal and psychotic symptoms. This information, in turn, will provide important evidence validating the early prodromal phases as critical periods for testing the effectiveness of primary preventive intervention programs and may suggest strategies for the development of novel preventive treatments that can correct or compensate for the specific neurodevelopmental and psychological changes associated with the formation of psychotic symptoms during late adolescence and early adulthood.

A major impediment that has particularly hindered the success of many such investigations to date is that of sample ascertainment. The low incidence of Schizophrenia and the lack of early, specific signs of vulnerability renders the identification of those who are most at risk extraordinarily difficult. As such, it is a significant challenge to amass samples that are sufficiently powered to address questions of interest with regard to neurobiological, genetic, and psychosocial risk factors that distinguish individuals who develop Schizophrenia from those who develop other psychotic disorders from those whose symptoms remain stable or improve (e.g., Heinssen, Cuthbert, Breiling, Colpe, & Dolan-Sewell, 2003). Such difficulties have led to the development of large-scale collaborative efforts in which data are pooled across multiple sites to allow researchers to better delineate risk factors for psychosis, as such efforts will substantially increase the power for hypothesis testing

available to any one site alone. Pooling of databases across international sites will allow investigators to answer questions of fundamental importance regarding early detection, prediction, and prevention, which could not otherwise be resolved within a reasonable time frame.

Identification of Neural Endophenotypes

Given recent dramatic advances in molecular genetics, there has been a major shift in the focus of psychiatric genetic investigations from investigating patterns of familial transmission to localizing genes underlying mental disorders using genetic linkage and association strategies (Merikangas & Risch, 2003). Although early successes of linkage studies of Mendelian diseases (see Risch, 2000, for a review) engendered optimism that this approach would also be successful for complex psychiatric disorders such as Schizophrenia, efforts to date have proved largely unsuccessful (Glazier, Nadeau, & Aitman, 2002). Progress on this front has been hindered by complex patterns of inheritance, as well as diagnostic heterogeneity and imprecision (Freimer & Sabatti, 2003). Conventional diagnostic phenotypes are marked by such heterogeneity and overlap that genomic analyses using current syndrome definitions are questionable. As discussed in this chapter, the development of endophenotypes—phenotypic traits or markers proposed to represent more direct expressions of underlying genes—may yield far more informative results than studies of aggregate psychiatric phenotypes (Gottesman & Gould, 2003). As such, an endophenotype-based approach is likely to aid in unraveling the complexity of transmission of complex mental disorders such as Schizophrenia.

With revisions to our current diagnostic classification system (*Diagnostic and Statistical Manual of Mental Disorders*, fifth edition; American Psychiatric Association, 2000) under way, it is critical that scientific evidence be better utilized in its development (Kupfer, First, & Regier, 2002). Several investigators in the field have highlighted the need to increasingly strive for classification that more closely represents expression of underlying biologic systems (Merikangas & Risch, 2003). For example, although Schizophrenia and bipolar disorder have traditionally been viewed as distinct disorders, recent work has revealed substantial familial coaggregation and overlap in the genomic regions showing linkage and association with these two disorders (Badner & Gershon, 2002; Berrettini, 2003; Murray et al., 2004). Elucidating the specific genetic and neural mechanisms influencing susceptibility to and expression of these illnesses, and explaining the nature of the

overlap between them, is critical to understanding the necessary and sufficient conditions for overt psychosis and to the identification of underlying genes. As the accumulation of genomic and gene expression knowledge accelerates, the ability to use more refined neural endophenotypes will be crucial to the success of these investigations.

Improving Treatment and Interventions for Schizophrenia: Using a Phenomics Approach

The generation of more discrete, quantifiable definitions of pathological phenotypes not only will inform investigations of genetic etiology, but is also likely to aid in the development of rational pharmacotherapies for Schizophrenia. Despite major advances in neuroscience, drug discovery, and pharmacogenomics, the treatments currently available for Schizophrenia have only limited effectiveness. Existing diagnoses rely on symptoms far removed from drug targets, such that the discovery of new treatments is almost always serendipitous. Defining new phenotypes of the disorder at a neural-systems level, with links to drug mechanisms-of-action and patterns of gene expression, could yield dramatic advances in neuropsychiatric therapeutics, such as those that have resulted from the identification of neuropathological and neurochemical targets in Parkinson's disease (DeKosky & Marek, 2003; Samii, Nutt, & Ransom, 2004).

A variety of approaches, ranging from interview-based assessments and neurocognitive testing to functional neuroimaging and even measurements of gene expression have generated a diversity of candidate phenotypes for research. A focus on endophenotypes examined through a multidisciplinary approach that capitalizes on convergent technologies, from molecular to behavioral, is likely to accelerate the discovery of new treatments.

In particular, cognitive abnormalities, known to be a core feature of Schizophrenia, offer quantitative phenotypes for genomic studies and clinical trials and provide clear bridges to connect to informative neural systems models. Cognitive constructs are highly quantitative, enabling phenotypic assessments to be conducted with the high throughput necessary for adequately powered genomic association studies and multicenter clinical trials.

Phenomics is an innovative new direction in the field, in which a multidisciplinary approach is utilized to examine candidate disease phenotypes that can be measured not only across syndromes but across species, and may be used in validity testing at multiple physiological levels, including the neural systems and cellular and molecular levels. This approach may open innovative prospects for both pathophysiological modeling and drug discovery. Combin-

ing information across multiple levels of phenotypic expression, with modeling of the neural systems that support these functions, can advance definitions of phenotypes that can prompt various new research threads and raises the promise of novel and even genomically targeted therapeutic approaches. This is a time in which the field may very well be on the verge of multiple breakthroughs with regard to our understanding of Schizophrenia; further focus on enhancing methods for the study of new phenotypes is likely to be vital for accelerating the pace of discovery.

RESEARCH NEEDED ON OTHER HYPOTHESES 591

CONCLUSIONS 592

REFERENCES 593

This chapter reviews 10 years of research into a developmental taxonomy of antisocial behavior that proposed two primary hypothetical prototypes: life-course-persistent versus adolescence-limited offenders. The taxonomic theory was

Preparation of this chapter was supported by grants from the U.S. National Institute of Mental Health (MH45070 and MH4941) and the British Medical Research Council (G9806489 and G0100527). Terrie Moffitt is a Royal Society-Wolfson Merit Award Holder. This chapter is an update of an earlier, shorter chapter published in *The Causes of Conduct Disorder and Serious Juvenile Delinquency*, by B. Lahey, T. E. Moffitt, and A. Caspi, 2003, New York: Guilford Press.

fully articulated for the first time in a chapter written for the first edition of *Developmental Psychopathology* (Caspi & Moffitt, 1995). Therefore, it is particularly appropriate to review for the second edition the research published since then. According to the taxonomic theory, life-course-persistent offenders' antisocial behavior has its origins in neurodevelopmental processes; it begins in childhood and continues persistently thereafter. In contrast, adolescence-limited offenders' antisocial behavior has its origins in social processes; it begins in adolescence and desists in young adulthood. According to the theory, life-

course-persistent antisocial individuals are few, persistent, and pathological. Adolescence-limited antisocial individuals are common, relatively transient, and near normative (Moffitt, 1990, 1993, 1994, 1997, 2003).

Discussions in the literature have pointed out that if the taxonomic theory is proven accurate, it could usefully improve classification of subject groups for research (Nagin, Farrington, & Moffitt, 1995; Silverthorn & Frick, 1999; Zucker, Ellis, Fitzgerald, Bingham, & Sanford, 1996), focus research into antisocial personality and violence toward the most promising causal variables (Brezina, 2000; Lahey, Waldman, & McBurnett, 1999; Laucht, 2001; Osgood, 1998), and guide the timing and strategies of interventions for delinquent types (Howell & Hawkins, 1998; Scott & Grisso, 1997; Vermeiren, 2002). Several writers have extracted implications for intervention from the taxonomy. Howell and Hawkins observed that preventing life-course-persistent versus adolescence-limited antisocial behavior requires interventions that differ in both timing and target. Preventing life-course-persistent lifestyles requires early childhood interventions in the family. In contrast, adolescence-limited offending ought to be prevented by treating adolescents individually to counteract peer influence (instead of in groups that facilitate deviant peer influence; Dishion, McCord, & Poulin, 1999). Scott and Grisso argued compellingly that the juvenile justice system should identify adolescence-limited delinquents and give them room to reform. Surveys of juvenile court judges and forensic psychologists reveal that the offender characteristics they rely on to recommend a juvenile for transfer to adult court match the characteristics that distinguish life-course-persistent delinquents (Slaekin, Yff, Neumann, Leistico, & Zalot, 2002). In contrast, Scott and Grisso argue that sending life-course-persistent delinquents to adult court is inappropriate because the cognitive deficits typical of these delinquents render them unlikely to meet legal criteria for competency to stand trial.

The taxonomy of childhood- versus adolescent-onset antisocial behavior has been codified in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 1994), presented in many abnormal psychology and criminology textbooks, and invoked in the National Institute of Mental Health (2000) fact sheet *Child and Adolescent Violence Research*, the U.S. Surgeon General's (2001) report *Youth Violence*, the World Health Organization's (2002) *World Report on Violence and Health*, and the National Institutes of Health's (2004) *State-of-the-Science Consensus Statement on Preventing Violence*. But is it valid?

The reader is referred to two prior publications that articulate the main hypotheses derived from this taxonomic

theory. The first article published that proposed the two prototypes and their different etiologies ended with a section headed "Strategies for Research," which described predictions about epidemiology, age, social class, risk correlates, offense types, desistance from crime, abstainers from crime, and the longitudinal stability of antisocial behavior (Moffitt, 1993, pp. 694–696). The article specified which findings would disconfirm the theory. A version published elsewhere specified disconfirmable hypotheses about sex and race (Moffitt, 1994). When these hypotheses from the taxonomy were put forward 10 years ago, none of them had been tested, but since then several have been tested by us and by others. This chapter reviews the results of that research, as of summer 2004, and points out where more research is needed.

A BRIEF INTRODUCTION TO THE TWO PROTOTYPES

In a nutshell, we suggested that life-course-persistent antisocial behavior originates early in life, when the difficult behavior of a high-risk young child is exacerbated by a high-risk social environment. According to the theory, the child's risk emerges from inherited or acquired neuropsychological variation, initially manifested as subtle cognitive deficits, difficult temperament, or hyperactivity. The environment's risk comprises factors such as inadequate parenting, disrupted family bonds, and poverty. The environmental risk domain expands beyond the family as the child ages, to include poor relations with people such as peers and teachers. Opportunities to learn prosocial skills are lost. Over the first 2 decades of development, transactions between the individual and the environment gradually construct a disordered personality with hallmark features of physical aggression and antisocial behavior persisting to midlife. The theory predicts that antisocial behavior will infiltrate multiple adult life domains: illegal activities, problems with employment, and victimization of intimate partners and children. This infiltration diminishes the possibility of reform.

In contrast, we suggested that adolescence-limited antisocial behavior emerges alongside puberty, when otherwise ordinary healthy youngsters experience psychological discomfort during the relatively role-less years between their biological maturation and their access to mature privileges and responsibilities, a period we called the "maturity gap." They experience dissatisfaction with their dependent status as a child and impatience for what they anticipate are the privileges and rights of adulthood. While young people are in this gap, it is virtually normative for them to find

the delinquent style appealing and to mimic it as a way to demonstrate autonomy from parents, win affiliation with peers, and hasten social maturation. However, because their predelinquent development was normal, most adolescence-limited delinquents are able to desist from crime when they age into real adult roles, returning gradually to a more conventional lifestyle. This recovery may be delayed if the antisocial activities of adolescence-limited delinquents attract factors we called “snares,” such as a criminal record, incarceration, addiction, or truncated education without credentials. Such snares can compromise the ability to make a successful transition to adulthood.

The literature contains other theoretical statements about early- versus late-onset antisocial behavior, but our theory differed in three ways. First, it offered not only an account of onset processes but also included an explanation of the developmental processes leading to the maintenance of and desistance from antisocial behavior. Second, whereas other theories emphasize inept parenting as the primary cause initiating life-course-persistent antisocial behavior, this theory argued that children’s own characteristics are a primary force in the transactions between child and environment. Third, whereas other theories emphasize poor parental supervision and monitoring as the primary cause of adolescence-limited delinquent behavior, this theory argued that adolescent-limited delinquency emerges from the age-appropriate developmental process of building autonomy, in which young people move away from childhood parent-child relationships and toward mature peer-to-peer relationships.

THE HYPOTHESIS THAT LIFE-COURSE-PERSISTENT ANTISOCIAL DEVELOPMENT EMERGES FROM EARLY NEURODEVELOPMENTAL AND FAMILY ADVERSITY RISK FACTORS

The original hypothesis about childhood risk specified that predictors of life-course-persistent antisocial behavior should include “health, gender, temperament, cognitive abilities, school achievement, personality traits, mental disorders (e.g., hyperactivity), family attachment bonds, child-rearing practices, parent and sibling deviance, and socioeconomic status, but not age” (Moffitt, 1993, p. 695).

Our own tests of this hypothesis have been carried out in the Dunedin Multidisciplinary Health and Development Study, a 32-year longitudinal study of a birth cohort of 1,000 New Zealanders. A full description of the Dunedin Study and the New Zealand research setting can be found in

Moffitt, Caspi, Rutter, and Silva (2001). These tests have examined childhood predictors measured between ages 3 and 13, operationalizing the two prototypes of antisocial behavior using both categorical and continuous statistical approaches. These studies showed that the life-course-persistent path was differentially predicted by individual risk characteristics, including undercontrolled temperament measured by observers at age 3, neurological abnormalities and delayed motor development at age 3, low intellectual ability, reading difficulties, poor scores on neuropsychological tests of memory, hyperactivity, and slow heart rate (Jeglum-Bartusch, Lynam, Moffitt, & Silva, 1997; Moffitt, 1990; Moffitt & Caspi, 2001; Moffitt, Lynam, & Silva, 1994). The life-course-persistent path was also differentially predicted by parenting risk factors, including teenage single parent, mother with poor mental health, and mother who was observed to be harsh or neglectful, as well as by experiences of harsh and inconsistent discipline, much family conflict, many changes of primary caretaker, low family socioeconomic status (SES), and rejection by peers in school. In contrast, study members on the adolescence-limited path, despite being involved in teen delinquency to the same extent as their counterparts on the life-course-persistent path, tended to have backgrounds that were normative, or sometimes even better than the average Dunedin child’s (Moffitt & Caspi, 2001). A replication of this pattern of differential findings was reported by a study of 800 children followed from birth to age 15 years (Brennan, Hall, Bor, Najman, & Williams, 2003). An early-onset persistent antisocial group, an adolescent-onset antisocial group, and a nonantisocial group were identified. Measured biological risks (e.g., neuropsychological test deficits at age 15) and childhood social risks (e.g., harsh discipline, maternal hostility), and an interaction between these two risks predicted membership in the early-onset persistent group, but membership in the adolescent-onset group was unrelated to childhood social risks or biological risks.

The Dunedin findings about differential neurodevelopmental and family risk correlates for childhood-onset versus adolescent-onset offenders are generally in keeping with findings reported from other samples in Australia, Canada, England, Mauritius, New Zealand, Norway, Russia, Sweden, and several states in the United States. These studies operationalized the types using a variety of conceptual approaches, many different measures of antisocial behaviors, and very different statistical methods (Aguilar, Sroufe, Egeland, & Carlson, 2000; Arseneault, Tremblay, Boulerice, & Saucier, 2002; Brennan et al., 2003; Chung, Hill, Hawkins, Gilchrist, & Nagin, 2002; Dean, Brame, & Piquero, 1996; Donnellan, Ge, & Wenk, 2000; Fergusson,

Horwood, & Nagin, 2000; Kjelsberg, 1999; Kratzer & Hodgins, 1999; Lahey et al., 1998; Magnusson, af Klintberg, & Stattin, 1994; Maughan, Pickles, Rowe, Costello, & Angold, 2001; Mazerolle, Brame, Paternoster, Piquero, & Dean, 2000; McCabe, Hough, Wood, & Yeh, 2001; Nagin et al., 1995; Nagin & Tremblay, 1999, 2001b; Patterson, Forgatch, Yoerger, & Stoolmiller, 1998; Piquero, 2001; Piquero & Brezina, 2001; Raine et al., 2005; Raine, Yaralian, Reynolds, Venables, & Mednick, 2002; Roeder, Lynch, & Nagin, 1999; Ruchkin, Koposov, Vermeiren, & Schwab-Stone, 2003; Tibbetts & Piquero, 1999; Tolan & Thomas, 1995; Wiesner & Capaldi, 2003). Each of these studies added support for the taxonomy's construct validity by reporting differential correlates for early-onset/persistent antisocial behavior versus later-onset/temporary antisocial behavior. However, at least one research team found mixed evidence for the taxonomy (cf. Brame, Bushway, & Paternoster, 1999, versus Paternoster & Brame, 1997).

Other studies, although not necessarily presented as a formal test of the two types, have reported findings consonant with our predictions about the types' differential childhood risks. For example, children's hyperactivity interacts with poor parenting skills to predict antisocial behavior that has an early onset and escalates to delinquency (Patterson, DeGarmo, & Knutson, 2000), an interaction that fits the hypothesized origins of the life-course-persistent path. Other studies have reported that measures reflecting infant nervous system maldevelopment interact with poor parenting and social adversity to predict aggression that is chronic from childhood to adolescence (Arseneault et al., 2002). Measures indexing infant nervous system maldevelopment and social adversity also interact to predict early-onset violent crime (Raine, Brennan, & Mednick, 1994; Raine, Brennan, Mednick, & Mednick, 1996) but do not predict nonviolent crime (Arseneault, Tremblay, Boulerice, Seguin, & Saucier, 2000; Raine, Brennan, & Mednick, 1997). Two additional findings are consistent with our prediction that infant nervous system maldevelopment contributes to long-term life-course-persistent antisocial outcomes. First, prenatal malnutrition has been found to predict adult Antisocial Personality Disorder (Neugebauer, Hoek, & Susser, 1999). Second, adults with Antisocial Personality Disorder exhibit two nervous system abnormalities attributable to disruption of brain development in early life: enlargement of the corpus callosum, assessed by structural magnetic resonance imaging, and abnormal corpus callosum connective function, assessed by divided visual field tests (Raine et al., 2003).

Our differential risk prediction encountered a particular challenge from a longitudinal study of a low-SES Minneapolis sample (Aguilar et al., 2000). This research team observed that differences between their childhood-onset and adolescent-onset groups were not significant for neurocognitive and temperament measures taken prior to age 3, although they found that significant differences did emerge later in childhood. The authors inferred that childhood psychosocial adversity is sufficient to account for the origins of life-course-persistent antisocial behavior, which is similar to Patterson and Yoerger's (1997) thesis that unskilled parenting is sufficient to account for the early-onset antisocial type. Such exclusive socialization hypotheses are probably not defensible in view of emerging evidence that the life-course-persistent pattern of antisocial behavior appears to have substantial heritable liability (DiLalla & Gottesman, 1989; Eley, Lichtenstein, & Moffitt, 2003; Taylor, Iacono, & McGue, 2000), a finding we revisit later in this chapter. The lack of significant early childhood differences in the Minneapolis study may have arisen from methodological features of the study, including the unrepresentative and homogeneous nature of the sample (all high-risk, low-SES families) and irregular sex composition of the groups (more females than males were antisocial), or weak psychometric qualities of the infant measures (unknown predictive validity). Infant measures are known for their poor predictive validity (McCall & Carriger, 1993), and thus it is possible that the failure of the infant measures to predict the life-course-persistent path is part of such measures' more general failure to predict outcomes.

One study has reported that difficult temperament assessed at age 5 months distinguished a group of children who showed a trajectory of high rates of physical aggression, as compared to cohort peers, across ages 17, 30, and 42 months (Tremblay et al., 2004). However, until this cohort of 572 infants is followed beyond age 3.5 years into adolescence, we cannot be confident that they represent youngsters on the life-course-persistent pathway. Other studies have reported a significant relation between life-course-persistent-type offending and problems known to be associated with neurocognitive and temperamental difficulties in infancy: perinatal complications, minor physical anomalies, and low birthweight (Arseneault et al., 2000, 2002; Kratzer & Hodgins, 1999; Raine et al., 1994; Tibbetts & Piquero, 1999). These studies illustrate desirable features for testing neurodevelopmental risks from the beginning of infancy for persistent antisocial behavior: large samples, representative samples, infant measures with proven predictive validity, and attention to interactions

between neurodevelopmental and social adversity (Cicchetti & Walker, 2003).

What Research Is Needed?

Research already documents that life-course-persistent antisocial behavior has the predicted neurodevelopmental correlates in the perinatal and middle childhood periods, but the Aguilar et al. (2000) study remains the only one that has reported objective measures of infants' temperament and neurocognitive status prior to age 3 years, and it did not find the associations predicted by the theory. This study constitutes an important challenge that must be taken seriously, particularly as Brennan et al. (2003) also found no significant connection between temperament or vocabulary assessed in early life and early-onset persistent aggression. Clearly, more research is needed to fill in the critical gap between birth and age 3 years. This might be accomplished by following up the antisocial outcomes of infants tested with newer neurocognitive measures having documented predictive validity, such as the infant attention-habitation paradigm (Sigman, Cohen, & Beckwith, 1997).

Another feature of life-course-persistent theory that needs testing is the argument that antisocial behavior becomes persistent because a child's early difficult behavior provokes harsh treatment or rejection from parents, teachers, and peers, which in turn promotes more difficult child behavior. Adoption and twin studies have documented an initial "child effect"; that is, children carrying a genetic liability to antisocial behavior provoke harsh responses from their parents (Ge et al., 1996; Jaffee, Caspi, Moffitt, Polo-Tomas, et al., 2004; O'Connor, Deater-Deckard, Fulker, Rutter, & Plomin, 1998; Riggins-Caspers, Cadoret, Knutson, & Langbehn, 2003). Such genetically informative studies should be followed up to ascertain whether this process, beginning with a child effect, ultimately leads to antisocial behavior that persists long term.

THE HYPOTHESIS THAT GENETIC ETIOLOGICAL PROCESSES CONTRIBUTE MORE TO LIFE-COURSE-PERSISTENT THAN ADOLESCENCE-LIMITED ANTISOCIAL DEVELOPMENT

Journalists have drawn the public's attention to families that appear to contain far more than their share of criminal family members for several generations (Butterfield, 1996, 2002). This concentration of crime in families has been confirmed by studies of large populations of families. In

general, fewer than 10% of the families in any community account for more than half of criminal offenses (Farrington, Barnes, & Lambert, 1996; Farrington, Jolliffe, Loeber, Stouthamer-Loeber, & Kalb, 2001; Rowe & Farrington, 1997). Moreover, research has shown that parental crime and parental psychopathology are more strongly associated with early-onset antisocial behavior than late-onset antisocial behavior among offspring (Moffitt & Caspi, 2001; Raine et al., 2005; Taylor et al., 2000). These findings seem to implicate a genetic influence on life-course-persistent antisocial behavior, but they could also be explained by social transmission of antisocial behavior within families. Therefore, we next review studies using genetically sensitive research designs to glean insights about life-course-persistent antisocial behavior. If genetic etiological processes contribute more to life-course-persistent than to adolescence-limited antisocial development, we would expect to find that estimates of genetic influence are larger for antisocial behaviors committed by young children and adults than for antisocial behaviors committed by adolescents.

DiLalla and Gottesman (1989) first observed that adult crime seemed to be more heritable than adolescent juvenile delinquency. Our 1993 paper (Moffitt, 1993, p. 694) agreed with these authors that if the life-course-persistent type's causal factors are partly inherited, and if most antisocial adults are life-course-persistent but most antisocial adolescents are not, then this could account for the observed greater genetic influence on individual differences in adult than adolescent samples. As it turns out, the lack of heritability among juveniles in the DiLalla and Gottesman review probably resulted from low power and insensitive measurement; in 1989, the entire literature of behavior genetic studies of juvenile delinquency consisted of fewer than 200 twin pairs, and the measure of antisocial behavior was conviction, a rare outcome for juveniles. Since then, a large number of better-designed behavioral genetic studies have proven that juvenile antisocial behavior is at least somewhat heritable. However, among these, four groups of studies provide circumstantial evidence that life-course-persistent antisocial behavior does have stronger heritable origins than adolescence-limited antisocial behavior.

The first group comprises four studies of large representative samples of very young twins. Because life-course-persistent antisocial behavior begins early in life, if it is genetically influenced we would expect high heritability coefficients from studies of very young children. Dionne, Tremblay, Boivin, Laplante, and Perusse (2003) report 58% heritability for aggression among Canadian 19-month-olds. Van den Oord, Verhulst, and Boomsma (1996) report 69%

heritability for aggression among Dutch 3-year-olds. In a different Dutch cohort, van der Valk, Verhulst, Stroet, and Boomsma (1998) report 50% heritability for externalizing behaviors among 2- to 3-year-old boys and 75% for girls. Arseneault et al. (2003) report heritabilities of 61%, 69%, and 76% among British 5-year-olds for ratings of antisocial behaviors made by observers, mothers, and teachers, respectively. These high estimates for very young twins are in contrast to the lower estimate of 41% heritability from a meta-analysis of older samples (Rhee & Waldman, 2002).

A second group of studies has identified the two subtypes on the basis of the heterogeneity in the phenotype, often using the Aggression and Delinquency narrow-band scales from the Child Behavior Checklist (CBCL; Achenbach, 1985). The Aggression scale is thought to be associated with the life-course-persistent prototype because it measures antisocial personality and physical violence and its scores are stable across development, whereas the Delinquency scale is associated with the adolescence-limited prototype because it measures rule breaking and its mean scores rise steeply during adolescence (Stanger, Achenbach, & Verhulst, 1997). In fact, both life-course-persistent and adolescence-limited young people engage in the behaviors on the Delinquency scale, but adolescence-limited young people are relatively more numerous, and if they have less genetic risk, then we would expect the Delinquency scale to yield lower heritability estimates than the Aggression scale. Twin and adoption studies of these scales report higher heritability for Aggression (around 60%) than Delinquency (around 30% to 40%), but the shared environment is significant only for the Delinquency scale (also around 30% to 40%; e.g., Deater-Deckard & Plomin, 1999; Edelbrock, Rende, Plomin, & Thompson, 1995; Eley, Lichtenstein, & Stevenson, 1999; but see Schmitz, Fulker, & Mrazek, 1995). The approach of contrasting two phenotypes within antisocial behavior was also taken by Viding and colleagues (Viding, Blair, Moffitt, & Plomin, 2005), who reported that genes influenced 81% of the variation in antisocial behavior among callous-unemotional children, but only 30% of variation among the other study children, who engaged in ordinary antisocial behaviors. A different approach to contrasting two heterogeneous phenotypes was followed by Arseneault et al. (2003), who found that antisocial behavior that was pervasive across settings was more heritable than antisocial behavior that was situational; heritability was 82% if a child's antisocial behavior was agreed on by four different reporters across settings at home and at school, but lower (28% to 51%) for antisocial behavior limited to one setting or one reporter.

A third group of studies has defined life-course-persistent antisocial behavior in terms of preadolescent onset, contrasting it against antisocial behavior that begins during the adolescent period. One study found early onset to be strongly familial and substantially heritable, in contrast to adolescent onset which was less familial and largely influenced by environment (Taylor et al., 2000). In a Swedish twin study, 5-year continuity from childhood to adolescence in the CBCL Aggression scale was largely mediated by genetic influences, whereas continuity in the Delinquency scale was mediated both by the shared environment and genetic influences (Eley et al., 2003).

A fourth group of studies has taken a developmental approach to the other end of the life span, defining life-course-persistent antisocial behavior in terms of presence in adolescence combined with subsequent persistence to adulthood Antisocial Personality Disorder. Two studies demonstrated that such persistent antisocial behavior was significantly more heritable than that limited to adolescence (Jacobson, Neale, Prescott, & Kendler, 2003; Lyons et al., 1995). These longitudinal studies are supported by a meta-analysis containing adolescent and adult samples assessed with similar measures of aggression, in which adult samples generated significantly higher heritability estimates, on average, than adolescent samples (Miles & Carey, 1997). Rhee and Waldman's (2002) meta-analysis did not find higher heritability for adults than adolescents, because in the pool of studies they examined, age was wholly confounded with reporting source; adolescent studies used rating scales, and adult studies used official crime records.

Taken together, the four groups of existing studies suggest that the pattern of antisocial behavior that (1) begins early in life, (2) is pervasive across settings, (3) is characterized by aggressive personality traits, (4) includes physical aggression, and (5) persists into adulthood is associated with relatively more genetic influence than is the pattern of later-onset, situational, transient delinquency. *What does this high heritability estimate mean?* It does not mean that environmental experiences have a negligible effect on life-course-persistent antisocial development. To the contrary, a heritability estimate, as calculated, reflects the additive effects of specific genes on a phenotype, but it also includes two types of interplay between genes and environments. Correlations between genes and environments (GrE) increase the heritability estimate if genes lead study members to encounter environments that in turn exacerbate the phenotype. Interactions between genes and environments (GxE) increase the heritability estimate when genes condition the effects of environments on the phenotype by

influencing study members' vulnerability or resistance to risky environments. When estimates of heritability are very large, this encourages researchers to look for GxE and GrE effects on that phenotype. Following from our taxonomic theory of life-course-persistent antisocial behavior, the genetic component of variation in antisocial behavior measured in early childhood ought to comprise not only the direct effects of genes, but also the effects of correlations between vulnerability genes and risky environments, and interactions between them as well.

Studies have documented the existence of correlations between children's genetic predisposition toward antisocial behavior and their rearing environments, or GrE. Specifically, three adoption studies and one twin study have now shown that children with a genetic liability for antisocial behavior tend to evoke harsher discipline from their parents than do children lacking this liability (Ge et al., 1996; Jaffee, Caspi, Moffitt, Polo-Tomas, et al., 2004; O'Connor et al., 1998; Riggins-Caspers et al., 2003). However, to our knowledge, no research has examined whether this evocative child effect in turn *exacerbates* levels of the children's antisocial behavior when they are followed over time. Evidence of exacerbation is necessary to answer whether gene-environment correlations increase estimates of heritability for antisocial behavior over and above any direct effects of genes.

There is somewhat better evidence that interactions between genetic and environmental risk, or GxE, contribute to the heritability of life-course-persistent antisocial behavior. We tested GxE in two studies of one of the strongest risk factors for persistent antisocial behavior: child maltreatment. The first study used data from our Environmental-risk Longitudinal Twin Study (called E-risk) to test whether the effect of maltreatment on risk for antisocial behavior was strongest among 5-year-olds who were at high genetic risk for it. The E-risk Study follows a representative 1994 to 1995 cohort of 1,116 British twin pairs and their families (Moffitt & the E-Risk Study Team, 2002). Each child's genetic risk for conduct problems was estimated as a function of his or her cotwin's Conduct Disorder status and the pair's zygosity. For example, a child whose monozygotic (MZ) twin already had Conduct Disorder was deemed at highest genetic risk, whereas a child whose dizygotic (DZ) twin had Conduct Disorder was at lower genetic risk, and a child whose MZ twin was free from conduct problems was at the lowest genetic risk of all. Results showed that the effects of maltreatment were most detrimental for the children at high genetic risk. The experience of maltreatment was associated with an increase of

2% in the probability of a Conduct Disorder diagnosis among young children at low genetic risk for Conduct Disorder but an increase of 24% among children at high genetic risk (Jaffee et al., 2005).

Our second study used data from the male members of the Dunedin cohort to test whether this general GxE effect could be specified for a particular candidate gene. We used Dunedin men's DNA to genotype a polymorphism in the gene encoding the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAOA). We selected this gene because it was known to be functional in the brain and it had earlier been related to aggression in mice and in a human family pedigree. MAOA genotype moderated the effect of maltreatment (Caspi et al., 2002). Of the severely maltreated children with a genotype conferring low levels of MAOA expression, 85% developed one or more antisocial outcomes, as measured at different stages in the life course (e.g., a childhood diagnosis of Conduct Disorder up to age 15, conviction for violent crimes between ages 17 and 26, antisocial personality traits at age 26, and diagnosed Antisocial Personality Disorder at age 26). In contrast, despite being maltreated, children with a genotype conferring high levels of MAOA expression were less likely to develop antisocial problems. Although individuals having the combination of low-activity MAOA genotype and maltreatment were only 12% of the birth cohort, they accounted for 44% of the cohort's convictions for violent crimes. This finding has been replicated and extended in the Virginia Study of Adolescent Twin Development. This study was able to control for the parents' antisocial histories to rule out the possibility that a family liability toward aggression jointly influenced parents' maltreating behavior and children's antisocial outcome (Foley et al., 2004). Together, the E-risk, Dunedin, and Virginia studies of GxE illustrate how the high heritability of the life-course-persistent form of antisocial behavior is played out in the transactions between a genetically vulnerable child and high-risk environment that were specified in the theory of life-course-persistent antisocial development.

What Research Is Needed?

It would be useful to ascertain the genetic and environmental architecture of individual differences in trajectories of antisocial behavior over time. Such trajectories could be derived in longitudinal studies of twins by applying semi-parametric mixture modeling tools to repeated measures of antisocial behavior (for explanations of these models, see Nagin et al., 1995; Nagin & Tremblay, 2001a; Roeder et al., 1999). The theory would predict stronger monozygotic

twin similarity for membership in a childhood-onset, life-course-persistent trajectory, but less twin similarity for membership in an adolescent-onset trajectory. Because no twin studies to our knowledge have yet followed a sample of twins from childhood to adulthood while measuring antisocial behavior, a study of twin similarity in developmental trajectories of antisocial behavior is yet in the future. However, genetically informative studies could examine as proxies the elements of crime careers that characterize the life-course-persistent type: early onset of antisocial acts, recidivistic physical aggression, and psychopathic personality traits. One study has attempted this approach and reported that genetic influence is very strong among children who exhibit a callous, unemotional personality style by age 7 years (Viding et al., 2005).

IS A THIRD GROUP NEEDED? CHILDHOOD-LIMITED AGGRESSIVE CHILDREN MAY BECOME LOW-LEVEL CHRONIC CRIMINAL OFFENDERS WITH PERSONALITY DISORDERS

The original theoretical taxonomy asserted that two prototypes, life-course-persistent and adolescence-limited offenders, account for the preponderance of the population's antisocial behavior and thus warrant the lion's share of attention by theory and research. However, our analyses revealed a small group of Dunedin study males who had exhibited extreme, pervasive, and persistent antisocial behavior problems during childhood, but who surprisingly engaged in only low to moderate delinquency during adolescence from age 15 to 18, not extreme enough to meet criteria for membership in the life-course-persistent group (Moffitt, Caspi, Dickson, Silva, & Stanton, 1996). Like the life-course-persistent offenders, they had extremely undercontrolled temperaments as 3-year-olds (Moffitt et al., 1996), and in childhood they, too, suffered family adversity and parental psychopathology and had low intelligence (unpublished analyses). The existence of a small group of boys who exhibit serious aggression in childhood but are not notably delinquent in adolescence has been replicated in the Pittsburgh Youth Survey, where they were called "childhood-limited" antisocial children (Raine et al., 2005). In the Pittsburgh cohort, too, these boys had many risk factors, including family adversity, parental psychopathology, and severe neuropsychological deficits.

This group was a surprise to the theory, because the theory argued that an early-onset chain of cumulative in-

teractions between aggressive children and high-risk environments will perpetuate disordered behavior. On that basis, we had predicted that "false positive subjects, who meet criteria for a stable and pervasive antisocial childhood history and yet recover (eschew delinquency) after puberty, should be extremely rare" (Moffitt, 1993, p. 694). When we discovered this group, we optimistically labeled it the "recovery group" (Moffitt et al., 1996). Many researchers, we among them, hoped that this group would allow us to identify protective factors that can be harnessed to prevent childhood aggression from persisting and becoming more severe. However, our study of this group has revealed no protective factors.

Researchers testing for the presence of the life-course-persistent and adolescence-limited types have since uncovered a third type that replicates across longitudinal studies, first identified in trajectory analyses of a British cohort (Nagin et al., 1995). This third group of offenders have been labeled "low-level chronics" because they have been found to offend persistently but at a low rate from childhood to adolescence (Fergusson et al., 2000) or from adolescence to adulthood (D'Unger, Land, McCall, & Nagin, 1998; Nagin et al., 1995). Persuaded by these findings, we followed up the so-called recovery group in the Dunedin cohort at age 26 to see if they might fit the low-level chronic pattern as adults. We found that recovery was clearly a misnomer, as their modal offending pattern over time fit a pattern referred to by criminologists as "intermittency," in which some offenders are not convicted for a period but then reappear in the courts (Laub & Sampson, 2001). This Dunedin group's long-term offending pattern closely resembles that of the low-level chronic offender.

Anticipating true recoveries from serious childhood Conduct Disorder to be extremely rare, the taxonomic theory had argued that teens who engage in less delinquency than predicted on the basis of their childhood conduct problems might have off-putting personal characteristics that excluded them from the social peer groups in which most delinquency happens. Consistent with this prediction, a group in the Oregon Youth Study, who showed high levels of antisocial behavior at age 12 that decreased thereafter, scored low as adolescents on a measure of involvement with pro-delinquency peers (Wiesner & Capaldi, 2003). In the Dunedin cohort followed up to age 26, the members of this low-level chronic group, unlike other cohort men, were often social isolates; their informants reported that they had difficulty making friends, none had married, few held jobs, and many had diagnoses of Agoraphobia and/or Social Phobia. Almost all social phobics meet criteria for

Avoidant, Dependent, and/or Schizotypal Personality Disorder (Alnaes & Torgersen, 1988), and we speculate that men in this group may suffer from these isolating personality disorders. As many as one-third of this group had diagnosable depression, their personality profile showed elevated neuroticism, and their informants rated them as the most depressed, anxious men in the cohort. This pattern, in which formerly antisocial boys develop into depressed, anxious, socially isolated men, resembles closely a finding from a British longitudinal study of males followed from ages 8 to 32. In that study, too, at-risk antisocial boys who became adult “false positives” (committing fewer crimes than predicted) had few or no friends, held low-paid jobs, lived in dirty home conditions, and had been described in case records as withdrawn, highly strung, obsessional, nervous, or timid (Farrington, Gallagher, Morley, St. Ledger, & West, 1988).

Robins (1966) is often quoted as having said that half of conduct problem boys do not grow up to have antisocial personalities. Such quotations are intended to imply that early conduct problems are fully malleable and need not be a cause for pessimism. However, less often quoted is Robins’s observation that conduct problem boys who do not develop antisocial personalities generally suffer other forms of maladjustment as adults. This is an assertion of “multifinality” in the poor outcomes of at-risk children (Cicchetti & Cohen, 1995). In the Dunedin birth cohort, 87 boys had childhood conduct problems (i.e., 47 in the life-course-persistent group and 40 in the so-called recovery group). Of these 87 males, only 15% ($n = 13$) seemed to have truly recovered as adults, escaping all adjustment problems measured in the study at age 26. Taken together, findings from Dunedin and the studies by Farrington and Robins are consistent with our taxonomic theory’s original assertion that childhood-onset antisocial behavior is *virtually always* a prognosticator of poor adult adjustment.

What Research Is Needed?

Several studies have detected an unexpected group, variously labeled “recoveries,” “childhood-limited,” or “low-level chronic offenders,” depending on how long the cohort was followed. However, few studies have been able to shed any light on their personal characteristics. The characteristics revealed so far are suggestive of Avoidant, Dependent, Schizotypal Personality Disorders and/or low intelligence, but these outcomes have not been directly measured in adulthood. It is important to know if this group has adult psychopathology to test the theory’s assertion that serious

childhood-onset antisocial behavior reliably predicts long-term maladjustment.

IS A FOURTH GROUP NEEDED? ADULT-ONSET ANTISOCIAL BEHAVIOR

On the basis of examining official data sources, some investigators have suggested that significant numbers of offenders first begin to offend as adults (Eggleston & Laub, 2002; Farrington, Ohlin, & Wilson, 1986). This would appear to challenge our developmental taxonomy’s assertion that two groups, life-course-persistent and adolescence-limited, suffice to account for the majority of antisocial participation across the life course. However, the observation that many antisocial individuals are adult-onset offenders appears to be largely an artifact of official measurement. Estimates of the age at which antisocial behavior begins depend on the source of the data. For example, in the Dunedin study, only 4% of boys had been convicted in court by age 15 years, but 15% had been arrested by police by age 15, and 80% had self-reported the onset of illegal behaviors by age 15 (Moffitt et al., 2001, chap. 7). This suggests that official data lag behind the true age of onset by a few years. Similar findings have emerged from other studies in other countries. For example, a Canadian survey showed that self-reported onset antedated conviction by about 3.5 years (Loeber & LeBlanc, 1990), and a U.S. survey showed that self-reported onset of “serious” delinquency antedated the first court contact by 2.5 years and onset of “moderate” delinquency antedated the first court contact by 5 years (U.S. Office of Juvenile Justice and Delinquency Prevention, 1998). In the Seattle Social Development cohort, the self-reported onset of crime antedated the first court referral by 2.4 years, and the study estimated that the average offender committed 26 crimes before his official crime record began (Farrington et al., 2003). These comparisons of data sources suggest that investigations relying on official data will ascertain age of onset approximately 3 to 5 years after it has happened. A 3- to 5-year lag is relevant because most studies have defined adult-onset offenders as those whose official crime record began at or after age 18 years (Eggleston & Laub, 2002).

It also is useful to note that whereas the 18th birthday may have marked adulthood for young people born before 1960, the 18th birthday falls only midway between puberty and adulthood for contemporary generations. This shift emerged because contemporary generations are experiencing a more protracted adolescence, lasting until the mid-

20s (Arnett, 2000) or even into the early 30s for the cohort born after 1970 (Ferri, Bynner, & Wadsworth, 2003; Furstenberg, Cook, Sampson, & Slap, 2002). Although adult-onset crime begins at age 18 in legal terms, in developmental terms for contemporary cohort samples, it begins sometime after age 25.

In contrast to studies using official crime records, self-report cohort studies show that fewer than 4% of males commit their first criminal offense after age 17 (Elliott, Huizinga, & Menard, 1989). Self-report studies of American and European cohorts agree (Junger-Tas, Terlouw, & Klein, 1994). By age 18, virtually all of the Dunedin study members had already engaged in some form of illegal behavior at some time, according to their self-reports (Moffitt et al., 2001). Only 9% of Dunedin males and 14% of females remained naïve to all delinquency by age 18, and only 3% of males and 5% of females first offended as an adult, between ages 18 and 21. These findings carry an important lesson for methodology in developmental research into antisocial behavior. “Adult-onset” offenders cannot be defined for study with any certainty unless self-reported data are available to rule out juvenile onset prior to participants’ first official contact with the judicial system. When self-report data are consulted, they reveal that onset of antisocial behavior after adolescence is extremely rare. This conclusion extends to serious and violent offending (Elliott, 1994).

One way to ascertain whether adult-onset offenders constitute a significant group for study is to apply semi-parametric modeling techniques (Nagin, 1999; Nagin & Tremblay, 2001a; Roeder et al., 1999) to identify trajectories within a population-representative cohort of individuals whose behavior has been followed into adulthood. Three studies have done so. The Dunedin study identified no adult-onset trajectory in self-reports of delinquency from ages 7 to 26 years (see Figure 15.1). The Oregon Youth Study identified no adult-onset trajectory in self-reports of offending from ages 12 to 24 years (Wiesner & Capaldi, 2003). The Cambridge Longitudinal Study identified no adult-onset trajectory in official crime records followed to age 32 for a cohort born in the 1950s (Nagin et al., 1995).

The original theoretical taxonomy asserted that two prototypes, life-course-persistent and adolescence-limited offenders, can account for the preponderance of the population’s antisocial behavior. After more than 10 years of research, this assertion appears to be correct. Some studies of the taxonomy have reported an adult-onset group (e.g., Kratzer & Hodgins, 1999). However, these studies used official crime data, and thus most of their adult-onset offend-

Figure 15.1 Twenty-year trajectories of conduct disorder symptoms among 525 Dunedin males.

ers would probably be revealed as adolescent-onset if self-report data were available. These so-called adult-onset offenders can probably be accommodated by the adolescence-limited theory because when studied, the alleged adult-onset group has not differed from ordinary adolescent offenders (Eggleston & Laub, 2002). Moreover, like adolescence-limited offenders, adult-onset offenders’ crime careers tend to be brief and not serious (Farrington et al., 1986). In our view, the existence of individuals whose official crime record begins after age 18 does not constitute a threat to the taxonomy.

THE HYPOTHESIS THAT ADOLESCENCE-LIMITED ANTISOCIAL BEHAVIOR IS INFLUENCED BY THE MATURITY GAP AND BY SOCIAL MIMICRY OF ANTISOCIAL MODELS

The original theory asserted that

individual differences should play little or no role in the prediction of short-term adolescent offending careers. Instead, the strongest predictors of adolescence-limited offending should be peer delinquency, attitudes toward adolescence and adulthood reflecting the maturity gap [such as a desire for autonomy], cultural and historical contexts influencing adolescence, and age. (Moffitt, 1993, p. 695)

Most research on the taxonomy to date has focused on testing hypotheses about the etiology of life-course-persistent offenders. Unfortunately, adolescence-limited offenders have been relegated to the status of a contrast group,

and the original hypotheses about the distinct etiology of adolescent-onset offending have not captured the research imagination. This is unfortunate because adolescent-onset offenders are quite common (one quarter of both males and females as defined in the Dunedin cohort) and their antisocial activities are not benign. They are found among adjudicated delinquents as well as in the general population (Scholte, 1999). Moreover, even if adolescence-limited individuals commit fewer violent offenses than life-course-persistent individuals, the size of the adolescence-limited group is much larger than the size of the life-course-persistent group, and as a result the adolescence-limited group can be expected to account for an important share of a society's serious and violent offenses. In Dunedin, life-course-persistent men (10% of the cohort) accounted for 53% of the cohort's 554 self-reported violent offenses at age 26, but adolescence-limited men (26% of the cohort) accounted for 29% of the cohort's violent offenses, a non-trivial amount of violence (Moffitt, Caspi, Harrington, & Milne, 2002).

Do adolescents find the maturity gap psychologically aversive, and does this motivate their newfound interest in delinquency? Aguilar et al. (2000) discovered that adolescent-onset delinquents experienced elevated internalizing symptoms and perceptions of stress at age 16, which may be consistent with the taxonomy's assertion that these adolescents experience psychological discomfort during the maturity gap. The theory suggested that this discomfort motivated adolescents to engage in antisocial behavior to seem older. In a study of the Gluecks' sample, adolescents' concerns about appearing immature increased their likelihood of delinquency (Zebrowitz, Andreoletti, Collins, Lee, & Blumenthal, 1998). One interesting ethnographic study has made use of the maturity gap to explain *kortteliralli*, the street-racing alcohol youth culture of Finland (Vaaranen, 2001). The Victoria Adolescence Project studied 452 adolescents and their parents to examine how young people negotiate the maturity gap (Galambos, Barker, & Tilton-Weaver, 2003). This study identified a group of 25% of adolescents who exhibited a cluster of characteristics they called "pseudo-maturity." These adolescents, relative to their age cohort, were characterized by more advanced biological/pubertal status, older subjective age ("I feel a lot older than my age"), elevated perceptions of self-reliance, more wishes to emulate older brothers (but not sisters), more older friends, a greater desire to be older ("I would like to look a lot older than my age"), more involvement in pop culture, and less involvement in school but more involvement with peers. This cluster was not associated with SES level. The study concluded that for a large proportion

of teens, pubertal maturation brings about a poor fit between their developmental stage and their social environment: "They are caught in the maturity gap" (Galambos et al., 2003, p. 262). Parent and self-reports confirmed that this pseudo-mature group of teenagers engaged in elevated rates of problem behaviors, as expected by the theory of adolescence-limited delinquency.

Do adolescence-limited teenagers want to be more like life-course-persistent offenders? The theory of adolescence-limited delinquency borrowed the concept of "social mimicry" from the field of ethology to explain how adolescents might mimic the antisocial behavior of life-course-persistent antisocial boys in their midst in an effort to attain the mature status embodied in the antisocial lifestyle. New developmental research has shown that when ordinary young people age into adolescence, they begin to admire good students less and to admire aggressive, antisocial peers more (Bukowski, Sippola, & Newcomb, 2000; Luthar & McMahon, 1996; Rodkin, Farmer, Pearl, & Van Acker, 2000). One sociometric study that followed 905 children from age 10 to 14 reported that the association between physical aggression and being disliked by peers dissolved during this age period; as they grew older, the teenagers came to perceive their aggressive age-mates as having higher social status and more influence (Cillessen & Mayeux, 2004). Moreover, during adolescence, young people who place a high value on conforming to adults' rules become unpopular with their peers (Allen, Weissberg, & Hawkins, 1989).

Our Dunedin studies documented that an increase in young teens' awareness of peers' delinquency antedates and predicts onset of their own later delinquency (Caspi, Lynam, Moffitt, & Silva, 1993). We also showed that the adolescence-limited path is more strongly associated with delinquent peers, as compared to the life-course-persistent path (Jeglum-Bartusch et al., 1997; Moffitt & Caspi, 2001). However, one study that traced peer affiliation trajectories concluded that peers were as influential for childhood-onset persistent offenders as for adolescent-onset offenders (LaCourse, Nagin, Tremblay, Vitaro, & Claes, 2003). In contrast, others have shown that delinquent peer influences directly promote increases in delinquency, specifically among young males whose antisocial behavior begins in adolescence (Simons, Wu, Conger, & Lorenz, 1994; Vitaro, Tremblay, Kerr, Pagani, & Bukowski, 1997). In contrast, these same studies suggest that among males whose antisocial behavior begins in childhood, the direction of influence runs the other way; the child's own early antisocial behavior promotes increases at adolescence in the number of delinquent peers who selectively affiliate

with him. This is consistent with our life-course-persistent theory's assertion that during adolescence, life-course-persistent antisocial boys become "magnets" for peers who wish to learn delinquency.

The most direct test of the adolescence-limited etiological hypothesis was carried out in the Youth in Transition Survey of 2,000 males (Piquero & Brezina, 2001). This study was introduced to the literature with lyrics from a song entitled "Eighteen" by rocker Alice Cooper that express the ennui of the maturity gap: "I'm in the middle without any plans, I'm a boy and I'm a man." The study tested the hypothesis that desires for autonomy promoted adolescent-onset offending. It found that, as predicted, the offenses committed by adolescence-limited delinquents were primarily rebellious (not physically aggressive) and that this rebellious offending was accounted for by the interaction between maturational timing and aspects of peer activities that were related to personal autonomy. However, one measure of youth autonomy in this study did not predict offending.

It is important to acknowledge that alternative accounts of late-onset delinquency have been put forward. In particular, Patterson and Yoerger (1997) outlined a learning model in which decreases in parents' monitoring and supervision when their children enter adolescence cause adolescents to begin offending. We had argued that although parents' monitoring and supervision were certainly negatively correlated with adolescent-onset delinquency, the direction of cause and effect was unclear, and our adolescence-limited theory would say that this correlation arises because teens' desires to gain autonomy via delinquency motivate them to evade their parents' supervision (Moffitt, 1993, p. 693). A longitudinal study of 1,000 Swedish 14-year-olds and their parents suggested that our interpretation is correct (Kerr & Stattin, 2000). Adolescents actively controlled their parents' access to information about their activities, and teens who took part in deviant behavior limited their parents' capacity to monitor them. The study showed that parents' efforts to supervise and monitor were not very effective in controlling their teenagers' activities, and could even backfire if teens felt controlled.

What Research Is Needed?

Clearly, there is not very much research testing whether measures of the maturity gap and social mimicry can account for adolescence-limited delinquency, so any new studies with this aim would add to our understanding. Agnew (2003) offers a cogent breakdown of maturity gap elements

that can be tested. Short-term longitudinal studies of young teens might ask if a developmental increase in attitudes rejecting childhood and favoring autonomy is correlated with a growing interest in and approval of illicit activities. Moreover, there is the curious fact that life-course-persistent antisocial individuals are rejected by peers in childhood but later become more popular with peers in adolescence. The theory of social mimicry predicted this shift in popularity, but more longitudinal research following individuals' changes in social standing is needed to understand it fully. Finally, we should consult historical and anthropological work to ascertain if historical periods and cultures characterized by a clearly demarcated transition from childhood dependency to adulthood rights and responsibilities are also characterized by relatively low levels of delinquency and adolescent rebelliousness.

THE HYPOTHESIS THAT ABSTAINERS FROM DELINQUENCY ARE RARE INDIVIDUALS WHO ARE EXCLUDED FROM NORMATIVE PEER GROUP ACTIVITIES IN ADOLESCENCE

If, as the theory says, adolescence-limited delinquency is normative adaptational social behavior, then the existence of teens who abstain from delinquency requires an explanation. In other words, if ordinary teens take up delinquent behavior, then teens who eschew delinquency must be extraordinary in some way. The original theory speculated that teens committing no antisocial behavior would be rare and that they must have either structural barriers that prevent them from learning about delinquency, no maturity gap because of early access to adult roles, or personal characteristics unappealing to other teens that cause them to be excluded from teen social group activities (Moffitt, 1993, pp. 689, 695). As noted earlier, research has shown that during adolescence, young people who place a high value on conforming to adults' rules become unpopular with their peers (Allen et al., 1989).

We have studied male abstainers in the Dunedin cohort. Consistent with the rarity prediction, the Dunedin cohort contained only a very small group of males who avoided virtually any antisocial behavior during childhood and adolescence; abstainers were fewer than 10% of the cohort (Moffitt et al., 1996). The very small size of this group has been confirmed in other samples. Only 13% of 17-year-olds in the National Longitudinal Survey of Youth replied that they had never done any of the survey's 13 offense items (Piquero, Brezina, & Turner, in press). Two longitudinal cohort studies used a theory-free method to characterize heterogeneous trajectories within repeated measures

of aggressive behavior: Nagin and Tremblay (1999) detected an abstainer trajectory from childhood to adolescence containing very few males, and Wiesner and Capaldi (2003) detected an abstainer trajectory from adolescence to adulthood containing even fewer males (5%).

The small group of Dunedin abstainers described themselves at age 18 on personality measures as extremely overcontrolled, fearful, interpersonally timid, and socially inept, and they were latecomers to sexual relationships (i.e., virgins at age 18). Dunedin abstainers fit the profile that Shedler and Block (1990) reported for youth who abstained from drug experimentation in a historical period when it was normative: overcontrolled, not curious, not active, not open to experience, socially isolated, and lacking social skills. Dunedin abstainers were unusually good students, fitting the profile of the compliant good student who, during adolescence, can become unpopular with peers (Allen et al., 1989; Bukowski et al., 2000). Other studies have suggested that abstention from delinquency and substance use during adolescence is associated with feeling socially isolated from peers (Dunford & Elliott, 1984), having few friends (Farrington & West, 1993), or being a loner (Tolone & Tieman, 1990). Such findings prompted Shedler and Block (1990, p. 627) to comment that abstention is “less the result of moral fiber or successful prevention programs than the result of relative alienation from peers and a characterological overcontrol of needs and impulses.”

Dunedin’s age-26 follow-up data confirmed that the teenage abstainers did not become so-called adult-onset offenders (Moffitt, Caspi, et al., 2002). Although their teenage years had been socially awkward for them, their style became more successful in adulthood. As adults they retained their self-constrained personality, had virtually no crime or mental disorder, were likely to have settled into marriage, were delaying children (a desirable strategy for a generation needing prolonged education to succeed), were likely to be college-educated, held high-status jobs, and expressed optimism about their own future.

Another study of abstainers from delinquency was conducted using 1,600 17-year-olds from the 1997 National Longitudinal Survey of Youth (Piquero, Brezina, et al., in press). Consistent with theoretical prediction, relative to participants in delinquency the abstainers were few in number, more closely monitored by their parents, more attached to teachers, and less physically mature, reported less autonomy, dated less, and were less involved with friends who drank, smoked, tried drugs, and cut classes. However, an unexpected new finding was that abstainers were not wholly friendless; rather, they reported that they

had prosocial peers who “go to church regularly,” “plan to go to college,” and “participate in volunteer work.” This study also attempted to test the theory’s prediction that abstainers have personalities that make them unattractive to peers, using an item called “sadness/depression” intended to assess a morose, uncheerful style unlikely to appeal to peers. However, the study found that sadness/depression was correlated with delinquent participation, not abstention. This test was ambiguous because the depression item probably did not measure the overcontrolled, incurious, timid, socially inept personality style thought to preclude delinquency. Thus, this study provided some modest support for the taxonomy’s view of abstainers as a minority that exists outside the social scene that creates opportunities for delinquency among the teen majority. Moreover, the study suggested the provocative new finding that abstainers do have friends, who are prosocial like themselves.

What Research Is Needed?

To our knowledge, our finding that abstainers are social introverts as teens remains to be confirmed or discounted by another study directly designed to test this hypothesis. Adolescent sociometric studies might ask if delinquent abstention is indeed correlated with unpopularity and social isolation. Further study of abstainers is critical for testing the hypothesis that adolescence-limited offenders’ delinquency is normative adaptational behavior by ordinary young people.

THE HYPOTHESIS THAT LIFE-COURSE-PERSISTENT AND ADOLESCENCE-LIMITED DELINQUENTS DEVELOP DIFFERENT PERSONALITY STRUCTURES

The original theory hypothesized the following about the development of life-course-persistent offenders:

Over the years, an antisocial personality is slowly and insidiously constructed, and accumulating consequences of the youngster’s personality problems prune away options for change. . . . A person-environment interaction process is needed to account for emerging antisocial behavior, but after some age, will the “person” main effect alone predict adult outcome? (Moffitt, 1993, p. 684)

Our Dunedin studies of adolescents’ personality characteristics measured at age 18 showed that the life-course-persistent path was differentially associated with weak bonds to family and with the psychopathic personality

traits of alienation, callousness, and impulsivity. In contrast, the adolescence-limited path at age 18 was differentially associated with a tendency to endorse unconventional values and with a personality trait called “social potency” (Moffitt et al., 1996). We assessed personality traits 10 years later at age 26, this time using not only self-reports but reports from informants who knew the Dunedin study members well (Moffitt, Caspi, et al., 2002). The self- and informant-reports concurred that the life-course-persistent men had more negative emotionality (were more stress-reactive, alienated, and aggressive) and they were less agreeable (had less social closeness, were more callous) compared to adolescence-limited men. Life-course-persistent men were no longer particularly impulsive at age 26, but the adolescence-limited men were still somewhat elevated on this scale at age 26. It appears from these repeated Dunedin assessments that the life-course-persistent pathway leads to a disordered antisocial personality structure resembling the psychopath: aggressive, alienated, and callous. Adolescence-limited men, in contrast, are unconventional, valuing spontaneity and excitement.

In another study, 4,000 California Youth Authority (CYA) inmates were given the California Personality Inventory (Gough, 1987) in the 1960s and then followed up into the 1980s (Donnellan, Ge, & Wenk, 2002). Taxonomy comparison groups were defined as early starters versus later starters, and as chronic adult arrestees versus those arrested less often. The early-starter, chronic arrestees could be discriminated by extreme personality scale scores, in particular low communality, little concern with impression, irresponsibility, low control of emotions, low achievement motivation, low socialization, low tolerance (hostile, distrustful), and low well-being. Early starters also scored higher than late starters on the Schizophrenia and Hypomania scales of the Minnesota Multiphasic Personality Inventory (Dahlstrom, Welsh, & Dahlstrom, 1972), two scales that measure a tendency to think in a confused and suspicious way (Ge, Donnellan, & Wenk, 2003). Using different instruments and different informants, these CYS findings echo our Dunedin findings, in which life-course-persistent offenders were disagreeable and high on negative emotionality.

What Research Is Needed?

To our knowledge, the personality correlates of the taxonomy have been examined in only two samples (Dunedin and CYA), so the finding of differential personality structures remains to be verified by wider replication. Moreover, the unanticipated Dunedin finding that many adolescence-

limited offenders are unconventional excitement-seekers raises the question of whether this approach-oriented personality style is present prospectively before they take up delinquency and is an individual-difference risk factor for adolescent onset. If so, that was not anticipated by the theory. Childhood temperament studies that have measured the approach style might follow up their participants to ask if approach predicts adolescent-onset delinquency. Longitudinal research is also needed to determine if and when the antisocial personality style becomes set, that is, able to predict adult antisocial outcomes alone, without any further environmental input.

THE HYPOTHESIS THAT LIFE-COURSE-PERSISTENT DEVELOPMENT IS DIFFERENTIALLY ASSOCIATED IN ADULTHOOD WITH SERIOUS OFFENDING AND VIOLENCE

The original theory predicted that life-course-persistent offenders, as compared to adolescence-limited offenders, would engage in a wider variety of offense types, including “more of the victim-oriented offenses, such as violence and fraud” (Moffitt, 1993, p. 695).

By the time the Dunedin cohort reached age 18, we reported that the life-course-persistent pathway was differentially associated with conviction for violent crimes (Jeglum-Bartusch et al., 1997; Moffitt et al., 1996), and the adolescence-limited pathway was differentially associated with nonviolent delinquent offenses (Jeglum-Bartusch et al., 1997). These Dunedin findings are buttressed by reports from other samples that physical aggression usually begins in childhood and seldom begins in adolescence (e.g., Brame, Nagin, & Tremblay, 2001). Moreover, we had shown that preadolescent antisocial behavior that was accompanied by neuropsychological deficits predicted greater persistence of crime and more violence up to age 18 (Moffitt et al., 1994).

Our follow-up at age 26 confirmed that life-course-persistent men as a group particularly differed from adolescence-limited men in the realm of violence, including violence against the women and children in their homes. This finding was corroborated with large effect sizes by data from multiple independent sources, including self-reports, informant reports, and official court conviction records (Moffitt, Caspi, et al., 2002). In a comparison of specific offenses, life-course-persistent men tended to specialize in serious offenses (carrying a hidden weapon, assault, robbery, violating court orders), whereas

adolescence-limited men specialized in nonserious offenses (theft less than \$5, public drunkenness, giving false information on application forms, pirating computer software). Life-course-persistent men accounted for 5 times their share of the cohort's violent convictions. Thus, although they were a small group (10% of males), they accounted for 43% of the cohort's officially sanctioned violent crime.

Domestic violence against women and children at home was specifically predicted to be an outcome of the life-course-persistent group (Moffitt, 1993). At the age-26 Dunedin follow-up, this group's scores were elevated on self-reported and official conviction measures of abuse toward women, both physical abuse (e.g., beating her up, throwing her bodily) and controlling abuse (e.g., stalking her, restricting her access to her friends and family). Because the Dunedin cohort has been interviewed repeatedly about illicit behaviors for many years, study members now trust the study's guarantee of confidentiality and can be asked questions about hitting children, with the expectation of valid responses. Life-course-persistent men were the most likely to report that they had hit a child out of anger, not in the course of normal discipline. Our finding that life-course-persistent offenders perpetrated more domestic violence was supported by the Christchurch study's finding that young adults with childhood-onset antisocial behavior engaged in significantly more violence against partners than did those with adolescent-onset antisocial behavior (Woodward, Fergusson, & Horwood, 2002). Similarly, a study of New York parolees reported that those defined as life-course-persistent based on a childhood-onset offense record engaged in twice as much domestic violence as parolees with an adolescent-onset offense record (Mazerolle & Maahs, 2002).

In general, a large empirical literature shows that the strongest long-term predictors of violence are the same predictors implicated by our theory of life-course-persistent offending: early-onset antisocial behavior, neurodevelopmental risk factors, and family risk factors (for a review, see Farrington, 1998). Moreover, research comparing violent crime versus general nonviolent delinquency has shown that violence is differentially predicted by birth complications (Raine et al., 1997), minor physical anomalies (Arseneault et al., 2000), difficult temperament (Henry, Caspi, Moffitt, & Silva, 1996), and cognitive deficits (Piquero, 2001), each of which is a hypothetical risk for life-course-persistent development (for a review, see Raine, 2002). The Christchurch study reported that people with serious childhood-onset conduct problems, compared to children without conduct problems, engaged

in 10 times more violent crime by age 25 (Fergusson, Horwood, & Ridder, 2005). The Patterns of Care Study of 1,715 service users ages 6 to 17 years compared childhood-onset versus adolescent-onset Conduct Disorder cases and reported that the childhood-onset group committed significantly more bullying but not more of the other physically aggressive Conduct Disorder symptoms (McCabe et al., 2001). However, this study did not have an adult follow-up. Lahey and colleagues (1998) reported more physical aggression associated with adolescent-onset than with childhood-onset Conduct Disorder.

What Research Is Needed?

The literature makes it clear that neurodevelopmental and family risks predict violence when it is measured on a continuum, but only a few studies have compared the adult violent outcomes of *groups* defined on the basis of early versus late antisocial onset. In addition, research is needed to clarify why life-course-persistent offenders are more violent. Our theory implies that verbal cognitive deficits may limit their options for handling conflict (a neuropsychological explanation), that they may have learned in their family that violence is an effective way to manage conflict (a social-cognition explanation), and that broken attachment bonds lead to alienation from their potential victims (an attachment explanation; Moffitt, 1994; Moffitt & Caspi, 1995). All of these explanations specify early childhood as a critical period influencing adult violence. But which, if any, of these explanatory processes are correct? Research using designs that control for genetic transmission of a predisposition to aggression in families has now documented that experiences in the family do promote childhood-onset aggression through processes that are environmentally mediated. Environmental effects on children's aggression have now been documented for exposure to parents' domestic violence (Jaffee, Moffitt, Caspi, Taylor, & Arseneault, 2002), being reared by an antisocial father (Jaffee, Moffitt, Caspi, & Taylor, 2003), being reared by a depressed mother (Kim-Cohen, Moffitt, Taylor, Pawlby, & Caspi, 2005), being a recipient of maternal hostility (Caspi et al., 2004), and being a victim of child maltreatment (Jaffee, Caspi, Moffitt, & Taylor, 2004). These studies controlled for familial liability to psychopathology, suggesting that the risk factors influence children through environmental experience. This information gives fresh impetus for research to uncover how these experiences are mediated via the child's thoughts and emotions to produce persistent aggression. Research is needed on mediating developmental processes, because findings will point to targets for intervention.

THE HYPOTHESIS THAT CHILDHOOD-ONSET ANTISOCIAL BEHAVIOR WILL PERSIST INTO MIDDLE ADULTHOOD, WHEREAS ADOLESCENT-ONSET ANTISOCIAL BEHAVIOR WILL DESIST IN YOUNG ADULTHOOD

Inherent in the name “life-course-persistent” is the assertion that the antisocial activities of these individuals will persist across the life course. Though the rest of the population may decrease its antisocial participation as it ages, the life-course-persistent individuals should remain at the top of the heap on antisocial behaviors. Thus, the taxonomy accepts that antisocial participation declines markedly in midlife; nonetheless, it expects rank-order stability, particularly on age-relevant measures of antisocial activity. To test the differential desistance prediction, it is necessary to follow a cohort’s antisocial behavior from childhood to adulthood, but only a few studies have done this.

We followed up the Dunedin cohort at age 26 (Moffitt, Caspi, et al., 2002) to test hypotheses critical to this part of the theory: Childhood-onset antisocial behavior, but not adolescent-onset antisocial behavior, should be associated in adulthood with antisocial personality and continued serious antisocial behavior that expands into maladjustment in work life and victimization of partners and children (Moffitt, 1993, p. 695). Followed to age 26, the adolescent-onset delinquents at 26 were still engaging in elevated levels of property offending and they had financial problems, but they did not show a pattern of serious offending. Interestingly, the adolescent-onset delinquents self-reported problems with mental health and substance dependence, but these difficulties were not corroborated by informants who knew them well. Consistent with the taxonomy’s predictions, the childhood-onset delinquents at age 26 were the most elevated on psychopathic personality traits, mental health problems, substance dependence, numbers of children sired, financial problems, work problems, domestic abuse of women and children, and drug-related and violent crimes.

In a study of 4,000 CYA inmates followed into their 30s, significantly more early starters than later starters continued offending past age 21, past age 25, and past age 31. Moreover, early onset and low cognitive ability significantly predicted which inmates continued to offend past age 31 (Ge, Donnellan, & Wenk, 2001). A different study of CYA offenders looked in depth at predictors of criminal career duration among 377 parolees released on average at age 24 and followed for 12 years (Piquero, Brame, & Lynam, 2004). This study found that criminal career dura-

tion was predicted by low tested cognitive abilities and by the interaction between childhood poverty status and cognitive ability. Similarly, a large Swedish study reported less crime in adulthood among offenders who possessed positive personal characteristics resembling the characteristics of Dunedin adolescence-limited offenders (Stattin, Romelsjo, & Stenbacka, 1997).

These findings were obtained using groups of adolescence-limited and life-course-persistent males defined by applying commonsense clinical cutoffs (e.g., Moffitt et al., 1996). However, in the past decade, new analytic methods have become available for ascertaining whether distinctive trajectories exist within a population of individuals whose behavior has been measured repeatedly during development (Nagin, 1999; Nagin & Tremblay, 2001a; Roeder et al., 1996). These new semiparametric methods offer several advantages over the clinical cutoffs approach. First, the methods are agnostic with respect to taxonomic theories, and thus results are relatively free from investigator bias. Second, the methods can search a longitudinal data set to ask whether there is indeed more than one developmental trajectory in it, as a taxonomy implies. Third, they can ascertain the relative goodness of fit of competing models having 1, 2, 3, 4, or more trajectories to ascertain whether the taxonomic theory has specified the right number of developmental subtypes in the population. Fourth, they generate output from the best-fitting model that reveals whether its trajectories rise and fall at ages specified by the theory. Fifth, they generate output about which study participants belong to which trajectory, making it possible to ascertain whether each trajectory group approximates its population prevalence as specified by the theory. It is important to keep in mind that what researchers put into the method determines what they can get out, and therefore testing the taxonomy of life-course-persistent and adolescence-limited antisocial behavior calls for representative samples, repeated measures taken at informative ages from childhood to adulthood, and measures of antisocial behavior that capture its heterotypic continuity across developmental periods. In these respects, the Dunedin data set, although not perfect, was pretty good fodder for the semiparametric method.

We applied this method to counts of Conduct Disorder symptoms assessed (via self-, mother-, and teacher-reports) for 525 male study members at ages 7, 9, 11, 13, 15, 18, 21, and 26 years. Conduct Disorder symptoms are fighting, bullying, lying, stealing, cruelty to people or animals, vandalism, and disobeying rules; three such symptoms earn a formal diagnosis. The model that best fit the Dunedin data detected the following groups (see Figure 15.1). A

life-course-persistent group, 7% of the cohort, had a fairly stable high trajectory, exhibiting between 4 and 7 antisocial symptoms at every age from 7 to 26 years. This group had more symptoms than any of the other groups at every age. A group whose trajectory resembled an adolescence-limited pattern began with 2 symptoms at age 7 but increased to a peak of 4.5 symptoms at age 18, and then decreased on a slight downward trajectory to 3.5 symptoms at age 26. A recovery group, 21% of the cohort (similar to the childhood-limited or low-level chronic groups described in an earlier section of this chapter), began with 6 symptoms at age 7 but decreased steadily with age and had only 1 symptom by ages 21 and 26. An abstainer group, 11%, had less than 1 symptom on average at every age. Two further trajectory groups were identified. The first of these took an adolescence-limited shape, but at a low level, and the second took a recovery shape, but also at a low level. For illustrative purposes, in Figure 15.1 these two groups were collapsed into a consistently low group, 47% of the cohort, which had 1 to 2 symptoms on average at each age. Thus, the best-fitting model bore a not unreasonable resemblance to the taxonomy. Differential outcomes for the trajectory groups mirrored the outcomes for the clinically defined Dunedin groups (Moffitt, Caspi, et al., 2002). Males on the adolescence-limited trajectory were still engaging in property offending and substance abuse but not serious offending at age 26. Males on the life-course-persistent trajectory were the most elevated at age 26 on mental health problems and substance dependence, numbers of children sired, financial and work problems, domestic abuse of women and children, and drug-related and violent crimes.

Other cohort studies have applied trajectory analysis to repeated measures of antisocial behavior from childhood to adulthood. A British longitudinal study followed official crime records for a 1950s birth cohort of 400 men to age 32 and detected chronic and adolescence-limited trajectories that showed the expected differential desistance (Nagin et al., 1995). Unexpectedly, offenders defined as adolescence-limited had desisted from criminal offending according to their official police records, but according to their self-reports they continued into their 30s to drink heavily and get into fights. The South Holland epidemiological study followed 2,000 Dutch children from age 4 to 30 years (Bongers, Koot, van der Ende, Donker, & Verhulst, in press). This study reported two trajectories of young people with high levels of externalizing problems, as assessed by the CBCL (Achenbach, 1985). One trajectory was normative and distinguished by increasing truancy and alcohol and drug use, but did not markedly increase the risk of adult offending. The other trajectory was characterized

by increasing oppositional behavior and hot temper and was associated with elevated risk of serious and violent adult offending. Low trajectories were also detected.

The Rutgers Health and Human Development Project followed its longitudinal sample into adulthood and reported a test of the taxonomy using nonparametric mixture modeling to detect trajectory groups (H. R. White, Bates, & Buyske, 2001). However, White et al.'s figure 1, showing delinquency trajectories for the resulting groups, suggests that the group labeled "persistent" in this study was in reality adolescence-limited, because this group's trajectory showed very low levels of offending at ages 12 and 28 but a very pronounced adolescent offending peak at age 18. This sample may not have contained life-course-persistent members, because it was recruited via random telephone dialing with an initial 17% rate of refusal to the phone call and afterward a 52% completion rate for enrollment in data collection. Families with life-course-persistent risk characteristics are known to be difficult to engage as research participants (Farrington, Gallagher, Morley, St. Ledger, & West, 1990), and therefore they were probably among those who did not take part in the Rutgers study. Given the strong possibility that groups were mislabeled in this study, it is unclear what to make of it vis-à-vis the taxonomy.

The Oregon Youth Study applied trajectory analysis to 200 males followed from age 12 to 24 (Wiesner & Capaldi, 2003). In addition to the abstainer trajectory and the decreasing trajectory discussed in earlier sections of this chapter, the analysis also yielded a group whose antisocial behavior was chronically at the cohort's highest level (life-course-persistent?) and a group whose antisocial behavior increased somewhat from age 12 to a peak at 19, and then decreased from age 20 to 24 (adolescence-limited?). It is not clear that Wiesner and Capaldi would agree with our characterization of their groups; indeed, they used different labels for them. In any case, although these two groups seemed fairly similar in late adolescence, they diverged at the study's age 23 to 26 outcome point, with the chronic group showing much higher levels of alcohol use, drug use, and depression symptoms, as well as more adult antisocial behavior (Wiesner, Kim, & Capaldi, in press).

One clear shortcoming of the available longitudinal data that have been used to test for the presence of life-course-persistent versus adolescence-limited subtypes is that the data are "right-hand censored"; in other words, study participants have generally been followed only until their 20s or 30s. What is needed is a cohort that represents the general population and that has been followed through the age period of risk for most criminal offending, up to midlife.

Such a cohort does not yet exist. However, in the absence of the ideal representative cohort, there is one important study that warrants our focus. Sampson and Laub (2003) reported a follow-up of half of the Gluecks' sample, those who were adolescent inmates in Massachusetts in the 1940s. The authors constructed a unique database of official criminal records for almost 500 men, covering the period from age 7 years to the end of each offender's life, up to age 70 years. The study was noteworthy for collecting nationwide FBI records and for attending to artifacts in crime records arising from periods of incarceration or the offender's premature death. The authors' analyses were motivated by their skepticism about the idea of prospectively predicting a group of offenders who will account for a disproportionate amount of society's serious crime. Sampson and Laub reported two findings from the study that they believed challenge this idea. First, they found that almost all of the men in the Gluecks' sample desisted from criminal offending sooner or later. Second, they found heterogeneity in adulthood crime career patterns within the sample of adolescent inmates, and they found that this heterogeneity was not explained by measures of childhood risk. Because the Sampson and Laub publication was represented as a challenge to the life-course-persistent taxonomy, we must take a closer look at whether or not these two findings discredit the taxonomy. In so doing, it is useful to consider the nature of the sample studied by Sampson and Laub. According to the taxonomy, virtually all of the men studied would have been regarded as candidates for the life-course-persistent subtype. They had been incarcerated as young adolescents in reform schools, a status reserved at that time for a very small fraction of a state's youth, those having established already by adolescence the most serious, persistent records of deviance that could not be controlled by parents or schools. It is well documented that as a group, the boys had backgrounds of marked family adversity, social disadvantage, and childhood antisocial conduct. Sampson and Laub note details about the sample that fit the life-course-persistent pattern, such as low mean IQ and mean first arrest at 11.9 years. Thus, this sample born in 1924 to 1932 probably comprised, relative to the much larger population of Boston males their age, a small subgroup who had started on the life-course-persistent pathway.

Sampson and Laub's (2003, p. 577) first finding was that the men in the Gluecks' sample desisted from criminal offending sooner or later: "Aging out of crime appears to reflect a general process." Unfortunately, Sampson and Laub misrepresented the taxonomy's prediction; they set up a straw prediction to test that life-course-persistent offenders should carry on committing crimes at the same

high rate from adolescence through old age and to their death. Clearly, this was never implied by the taxonomy, because it acknowledged the populationwide process of aging out of crime and explained that the term life-course-persistent antisocial behavior did not require crime in old age, but referred to the persistence of antisocial personality characteristics or antisocial behaviors within the family (Moffitt, 1993, p. 680). The taxonomy's actual prediction was that delinquents like the Gluecks' would continue offending well beyond the age when most young men in their cohort population desisted. The study followed only reform school boys, and thus it could not provide comparative data on crime careers for Boston men born 1924 to 1932, but it is known that desistance from delinquency in young adulthood was the norm for this cohort, which came of age in the postwar era of near full employment. In contrast to that norm, 84% of the study men were arrested between ages 17 and 24, 44% were arrested in their 40s, 23% were arrested in their 50s, and 12% were arrested in their 60s. The reform school sample's mean crime career length was 25.6 years. It seems reasonable to believe that such remarkable statistics do not also describe the rest of the male population of Boston. Thus, the study's results seem reasonably consistent with the taxonomy's prediction that boys who begin life on the life-course-persistent pathway will have unusually extended offending careers, thereby accounting for more than their share of the crime rate.

Sampson and Laub's (2003) second finding was of heterogeneity in adulthood crime career patterns within the Gluecks' sample. Again, the alternative hypothesis seems to be a straw man. The alternative would be that males who spent their youth and early adulthood on the life-course-persistent pathway can show no variation in subsequent offending during midlife and aging over a span of many years. Such uniformity is implausible, and the taxonomic theory did not make such a prediction. Within the Gluecks' sample, six trajectories emerged from a semiparametric group-based modeling analysis. Thus, the men, all of whom began on the life-course-persistent pathway, varied subsequently in their age at desistance from crime and in their rate of offending up to the point of their desistance. Of particular importance, child and family characteristics did not discriminate among these six trajectories. On the one hand, this failure of discrimination is not surprising given that the cohort members' childhood backgrounds were almost uniformly high-risk. On the other hand, this finding suggests that to the extent that different crime careers emerge during midlife within a group of life-course-persistent men, concurrent life experiences must account for the divergence. This would constitute an interesting extension to

the taxonomic theory on a topic it did not originally address: heterogeneity within life-course-persistent delinquents in the ways they age out of crime.

This study by Sampson and Laub (2003) was well executed and well intentioned. The authors were concerned about practitioners who have reified the life-course-persistent idea, treating it as if it describes a group having hard boundaries, made up of individual children who are easy to identify in early childhood and who deserve radical interventions to avert their inevitable destiny as predatory criminals. The authors' concern is well placed, and their efforts to dissuade such reification are laudable. To their credit, the authors point out that "the current bandwagon . . . is not consistent with the logic of Moffitt's actual argument" (p. 576). Nonetheless, to make their points, the authors inadvertently had to misrepresent the original taxonomy as having made predictions that it did not make. Here we set the record straight. Life-course-persistent delinquents do not have to be arrested for illegal crimes steadily up to age 70, but they do have to maintain a constellation of antisocial attitudes, values, and proclivities that affect their behavior toward others. Life-course-persistent delinquents do not have to live exactly the same crime trajectory as they age out of crime; it is interesting to learn how their lives diverge. Laub and Sampson (2003) are leading the way in researching these questions using qualitative as well as quantitative methods.

What Research Is Needed?

Overall, our theory's prediction that childhood-onset antisocial behavior persists longer into adulthood than adolescent-onset delinquency seems to be on fairly solid empirical footing. It has been known for decades that early onset of offending predicts a longer duration of crime career, and this association was recently affirmed by two careful reviews (Gendreau, Little, & Goggin, 1996; Krohn, Thornberry, Rivera, & LeBlanc, 2001). Nonetheless, the adolescence-limited groups in the Dunedin cohort and other cohorts continued to experience some adjustment problems as adults, and we need research to understand what accounts for this. The original taxonomy put forward the hypothesis that we should expect some adolescence-limited delinquents to recover to good adult adjustment later than others, and that this age variation might be explained by snares such as a conviction record that harms job prospects (Moffitt, 1993, p. 691). The idea is that engaging in even limited delinquency as a young person can diminish the probability of subsequent good outcomes, par-

ticularly if one is caught and sanctioned. Also important is the information emerging from the work of Laub and Sampson (2003) pointing to marked heterogeneity within the life-course-persistent group in middle and late life, suggesting that research into midlife turning-point experiences is needed. Overall, longitudinal studies are needed that follow the life-course-persistent, low-level chronic, abstainer, and adolescence-limited groups to reveal the very long-term implications of their experiences in the first 2 decades of life.

GENDER: THE HYPOTHESIS THAT MOST FEMALE ANTISOCIAL BEHAVIOR IS THE ADOLESCENCE-LIMITED TYPE

The original statement of the taxonomy asserted that the theory describes the behavior of females as well as it describes the behavior of males. The full text of the theory that included predictions about females was published as a book chapter that is not widely available (Moffitt, 1994). Therefore, we quote the original statement, written in January 1991:

The crime rate for females is lower than for males. In this developmental taxonomy, much of the gender difference in crime is attributed to sex differences in the risk factors for life-course persistent antisocial behavior. Little girls are less likely than little boys to encounter all of the putative initial links in the causal chain for life-course persistent antisocial development. Research has shown that girls have lower rates than boys of symptoms of nervous system dysfunction, difficult temperament, late verbal and motor milestones, hyperactivity, learning disabilities, reading failure, and childhood conduct problems. . . . Most girls lack the personal diathesis elements of the evocative, reactive, and proactive person/environment interactions that initiate and maintain life-course persistent antisocial behavior.

Adolescence-limited delinquency, on the other hand, is open to girls as well as to boys. According to the theory advanced here, girls, like boys, should begin delinquency soon after puberty, to the extent that they (1) have access to antisocial models, and (2) perceive the consequences of delinquency as reinforcing. . . . However, exclusion from gender-segregated male antisocial groups may cut off opportunities for girls to learn delinquent behaviors. . . . Girls are physically more vulnerable than boys to risk of personal victimization (e.g., pregnancy, or injury from dating violence) if they affiliate with life-course persistent antisocial males. Thus, lack of access to antisocial models and perceptions of serious personal risk may dampen the vigor of girls'

delinquent involvement somewhat. Nonetheless, girls should engage in adolescence-limited delinquency in significant numbers. (pp. 39–40)

The original theory thus proposed that (1) fewer females than males would become delinquent (and conduct disordered) overall and that (2) among delinquents, the percentage who are life-course-persistent would be larger for males than females. Following from this, (3) the majority of delinquent females will be of the adolescence-limited type, and (4) their delinquency will have the same causes as adolescence-limited males' delinquency.

These predictions were borne out in the Dunedin cohort (Moffitt & Caspi, 2001; Moffitt et al., 2001). As predicted, the male:female difference was very large for the life-course-persistent form of antisocial behavior (10:1) but negligible for the adolescence-limited form (1.5:1). Childhood-onset females had high-risk neurodevelopmental and family backgrounds, but adolescent-onset females did not, which documented that females and males on the same trajectories share the same risk factors. We have described the elements of the adolescence-limited causal pathway among Dunedin females, showing that each girl's delinquency onset is linked to the timing of her own puberty (Moffitt et al., 2001), that delinquent peers are a necessary condition for onset of delinquency among adolescent girls (Caspi et al., 1993; Caspi & Moffitt, 1991), and that an intimate relationship with an offender promotes girls' antisocial behaviors (Moffitt et al., 2001).

Few empirical tests of this taxonomy have compared how females and males fit the two developmental trajectories, but it appears that our findings about Dunedin females are broadly consistent with these previous studies. Fergusson and colleagues (2000, 2002), studying the Christchurch sample ($n = 1,000$), found that a single model described male and female trajectories of antisocial behavior, and the male to female ratio was 4:1 for early-onset, versus only 2:1 for late-onset subjects. Kratzer and Hodgins (1999), studying a Swedish cohort ($n = 13,000$), found similar childhood risk factors for males and females in the life-course-persistent group, and the male to female ratio was 15:1 for early-onset, versus only 4:1 for late-onset subjects. Mazerolle et al. (2000), studying a Philadelphia cohort ($n = 3,655$), reported that early onset signaled persistent and diverse offending for males and females alike. A longitudinal study of 820 girls analyzed with a semiparametric mixture model found a stable, highly antisocial group, but this group contained only 1.4% of the girls (Cote, Zoccolillo, Tremblay, Nagin, & Vitaro, 2001).

All studies concur that females are seldom childhood-onset- or life-course-persistent-type (the exception is Aguilar et al., 2000, whose early-onset group had as many girls as boys).

The application of our developmental taxonomy to females was questioned by Silverthorn and Frick (1999), who put forward a contrasting, female-specific theory. They suggested that despite the fact that girls' onset of antisocial behavior is delayed until adolescence, this adolescent-onset pathway in girls is not analogous to the adolescence-limited pathway in boys. Instead, this theory argued, all delinquent girls have the same high-risk causal backgrounds as life-course-persistent males. To evaluate this alternative hypothesis, we conducted analyses in the Dunedin study (Moffitt et al., 1996) using self-reports, mothers' reports, and teachers' reports of antisocial behavior to define girls on the adolescence-limited and life-course-persistent paths. This study resulted in two findings: First, the vast majority of female delinquents fit the adolescence-limited, late-starter pattern; second, the childhood backgrounds of these females who exhibited adolescent-onset antisocial behavior were like the backgrounds of adolescence-limited delinquent boys, normative and not pathological. The proposal from Silverthorne and Frick has also been tested in the African American Philadelphia cohort of the National Collaborative Perinatal Project (N. A. White & Piquero, in press), using official crime records to define adolescence-limited and life-course-persistent offenders. This study, too, reported that most female offenders followed the adolescence-limited pattern, and that female and male adolescence-limited offenders scored similarly, and better than life-course-persistent offenders, on measures of family and individual risk such as childhood cognitive ability. Similar conclusions were reached in the Patterns of Care Study of 300 children receiving services for Conduct Disorder (McCabe, Rodgers, Yeh, & Hough, 2004). Because the African American cohort and the Patterns of Care sample were selected for high-risk status, childhood-onset girls were found at higher prevalence than in the Dunedin cohort, which represents the general population.

These accumulating findings suggest that the two theories of the origins of life-course-persistent and adolescence-limited offending describe the developmental course of antisocial behavior across the sexes and irrespective of sex. Because few females have the risk factors for life-course-persistent development, this theory explains the wide sex difference in serious, persistent antisocial behavior. Because the risk factors for adolescence-limited offending are equal-opportunity, this theory explains the sex

similarity for nonserious, transient delinquency during the teenage years (Moffitt et al., 2001).

What Research Is Needed?

The dearth of gender comparisons originates from a pragmatic circumstance. An ideal test of this theory requires a large representative (nonclinical, nonadjudicated) sample followed longitudinally from childhood to adulthood with repeated measures of antisocial behavior. To date, few such studies have included females. It would be useful to have a large sample including both life-course-persistent and adolescence-limited girls in sufficient numbers to test all components of our theory. The new longitudinal study of Pittsburgh girls may help in this regard (Hipwell et al., 2002).

RACE: THE HYPOTHESIS THAT BOTH LIFE-COURSE-PERSISTENT AND ADOLESCENCE-LIMITED DEVELOPMENTAL PROCESSES ARE EXACERBATED BY SOCIETAL RACE PREJUDICE

The original statement of the taxonomy asserted that the theory applies to ethnic minority populations as well as to Whites. The discussion of race was published in a book that is not easy to obtain (Moffitt, 1994). Therefore, we paraphrase the original statement:

In the United States, the crime rate for black Americans is higher than the crime rate for whites. The race difference may be accounted for by a relatively higher prevalence of both life-course persistent and adolescence-limited subtypes among contemporary African Americans. Life-course persistent antisocials might be anticipated at elevated rates among black Americans because the putative root causes of this type are elevated by institutionalised prejudice and by poverty. Among poor black families, prenatal care is less available, infant nutrition is poorer, and the incidence of exposure to toxic and infectious agents is greater, placing infants at risk for the nervous system problems that research has shown to interfere with prosocial child development. To the extent that family bonds have been loosened and poor black parents are under stress . . . and to the extent that poor black children attend disadvantaged schools . . . for poor black children the snowball of cumulative continuity may begin rolling earlier, and it may roll faster downhill. In addition, adolescence-limited crime is probably elevated among black youths as compared to white youths in contemporary America. If racially segregated communities provide greater exposure to life-course persistent role models, then circumstances are ripe for black

teens with no prior behavior problems to mimic delinquent ways in a search for status and respect. Moreover, black young people spend more years in the maturity gap, on average, than whites because ascendancy to valued adult roles and privileges comes later, if at all. Legitimate desirable jobs are closed to many young black men; they do not often shift from having "little to lose" to having a "stake in conformity" overnight by leaving schooling and entering a good job. Indeed, the biological maturity gap is perhaps best seen as an instigator of adolescent-onset delinquency for black youths, with an economic maturity gap maintaining offending into adulthood. (p. 39)

Thus, the taxonomy expected that both life-course-persistent and adolescence-limited causal processes should work the same way in African American and White American groups, but any excess of offending among poor African American youth could be attributed to an excess of the risk factors for both delinquent subtypes. Our research with the Pittsburgh Youth Survey has documented that childhood risk factors associated with life-course-persistent offending (low IQ and impulsive undercontrol) are related to early-onset, frequent delinquent offending and physical aggression among Black and White males alike (Caspi et al., 1994; Lynam et al., 2000; Lynam, Moffitt, & Stouthamer-Loeber, 1993). However, these studies have not specifically divided Pittsburgh delinquents into childhood-versus adolescent-onset comparison groups (because the cohort of the Pittsburgh study having IQ and personality data was not followed beyond age 13).

We know of only a few studies that have directly compared life-course-persistent versus adolescence-limited offender patterns across races, and they seem to offer opposing findings. Donnellan et al. (2000) designated the taxonomy groups in 2,000 young adult CYA inmates. On a comprehensive set of measures of cognitive ability, life-course-persistent offenders scored below adolescence-limited offenders. However, this predicted finding of differential cognitive risk applied to adjudicated Whites and Hispanics but not to adjudicated African Americans. The opposite pattern of race differences emerged from a different study of 377 CYA offenders released on average at age 24 and followed for 12 years (Piquero et al., 2004). This study found that African American parolees had worse childhood poverty and lower cognitive test scores than White parolees, the interaction between poverty and low cognitive ability predicted longer criminal career duration, and this prediction was stronger among African American than White parolees.

A study of the Baltimore sample of the National Collaborative Perinatal Project was able to test for race differ-

ences in the etiological process hypothesized to underlie life-course-persistent antisocial behavior (Piquero, Moffitt, & Lawton, in press). Results showed that several variables helped to explain differences between Whites and Blacks in the level of chronic offending. However, although Black participants had higher mean levels of risk factors than Whites, the developmental processes predicting chronic offending were the same across groups defined by race. Specifically, low birthweight in combination with adverse familial environments predicted chronic offending from adolescence to age 33 among Whites and African Americans alike, although the effect size reached statistical significance among only African Americans, a pattern opposite that reported by Donnellan et al. (2000). Most, but not all, of these studies of African American cohorts fit our theory's notion that causal developmental processes are the same across racial groups, but that African Americans end up with higher levels of crime because they begin the processes with higher levels of risk factors.

One further set of studies is relevant. A study of the Philadelphia sample of the National Collaborative Perinatal Project, which includes only African American families, showed that childhood measures of school discipline problems and low tested IQ predicted a more serious offending career (Piquero & Chung, 2001). In this same Philadelphia African American cohort, low scores on an achievement test of cognitive ability predicted early onset and subsequent persistence of offending (McGloin & Pratt, 2003), and neuropsychological test scores at ages 7 to 8 years and 13 to 14 years predicted patterns of life-course-persistent offending to age 39 (Piquero & White, 2003). In the Providence sample of the National Collaborative Perinatal Project, Piquero and Buka (2002) found the expected higher prevalence of offenders among African Americans compared to Whites. However, crime career patterns such as the concentration of crimes in a few offenders and the significant prediction of adult crime from chronic juvenile delinquency, applied equally well to both races. It has been shown that earlier onset of delinquent offending among African American males predicts a more serious crime career (Piquero & Chung, 2001) and a longer duration of crime career (Piquero et al., 2004), which suggests that the life-course-persistent pattern applies to Black samples as well as White samples.

What Research Is Needed?

The theory asserted that life-course-persistent and adolescence-limited processes should apply to both Whites and ethnic minorities (neurodevelopmental and family risks

should predict the earlier onset, greater seriousness, and longer duration of antisocial behavior across racial groups, and the maturity gap and peer influences should predict late onset across racial groups). Together, these causal processes should be able to account for the elevated prevalence of delinquency among ethnic minorities because minority group members experience higher levels of both sets of risk factors. Rowe, Vazsonyi, and Flannery (1994) provide an explanation of how to test this.

Most of the studies of African Americans cited here used cohorts defined in the period between 1955 and 1980. Of course, only cohorts defined some time ago can yield information about the duration and seriousness of crime careers followed into the 3rd decade of life, but research on more contemporary cohorts is also needed.

There is one caveat: If the maturity gap lasts longer for African American young men than for Whites, this would make it difficult to distinguish the life-course-persistent from adolescence-limited groups in Black samples on the basis of chronic offending into adulthood. Therefore, researchers examining contemporary cohorts of ethnic minorities should operationalize the life-course-persistent and adolescence-limited groups using other distinguishing features, such as early childhood onset of conduct problems, antisocial personality traits, or recidivistic youth violence.

RESEARCH NEEDED ON OTHER HYPOTHESES

Before 1993, virtually no research compared delinquent subtypes defined on a developmental basis, but now this research strategy has become almost commonplace. Many research teams have assessed representative samples with prospective measures of antisocial behavior from childhood to adulthood, and this has enabled comparisons based on age of onset and persistence. Now that the requisite databases are available, other hypotheses derived from the original taxonomic theory need to be tested.

First, we suggested that childhood measures of antisocial behavior in longitudinal studies should be more highly correlated with adult measures than with adolescent measures of antisocial behavior (Moffitt, 1993, p. 695). This hypothesis derived from the taxonomy's assertion that the people participating in antisocial behavior in childhood and adulthood are the same people, but they are joined in adolescence by other people whose reasons for participation are different. If childhood measures did correlate with adult measures better than with adolescent measures, it would be a surprising violation of the so-called longitudinal law that measures taken closer together in time are

more strongly correlated than measures taken further apart in time. In the Dunedin study, we asked how closely age-3 undercontrolled temperament was associated with later antisocial diagnostic outcomes (controlling for sex). Age-3 undercontrol was a significant predictor of adult diagnoses 2 decades later: OR = 3.1 (CI = 1.3 –7.5) for age-26 Antisocial Personality Disorder and OR = 4.1 (CI: 2.0 to 8.4) for age-21 Conduct Disorder. However, the associations between age-3 temperament and adolescent diagnoses were not significant: OR = 1.7 (CI = 0.9 to 3.4) for age 15 Conduct Disorder and OR = 1.8 (CI = 0.9 to 3.8) for age 18 Conduct Disorder. The South Holland epidemiological study reported a similar finding: Antisocial behaviors assessed at ages 6 to 11 years predicted antisocial behaviors at ages 12 to 17 years only weakly (OR = 2.5), but predicted antisocial behavior at ages 20 to 25 years strongly (OR = 6.7; Donker, Smeenk, van der Laan, & Verhulst, 2003). More such tests of the hypothesis that childhood antisocial behavior predicts adult outcome better than adolescent outcome are needed.

Second, we speculated that adolescence-limited offenders must rely on peer support for crime, but life-course-persistent offenders should be willing to offend alone (although in adolescence, they serve as magnets for less expert offenders; Moffitt, 1993, p. 688). To our knowledge, this hypothesis has not been systematically examined.

Third, we suggested that snares (such as a criminal record, incarceration, addiction, and truncated education without credentials) should explain variation in the age at desistance from crime during the adult age period, particularly among adolescence-limited offenders (Moffitt, 1993, p. 691). One study reported that alcohol and cannabis dependence can ensnare young people in an antisocial lifestyle; most individuals' personal curve of antisocial participation from age 18 to 26 generally grows downward, but a spell of substance dependence temporarily deflects this curve upward (Hussong, Curran, Moffitt, Caspi, & Carrig, 2004). More such tests of the hypothesis that snares mediate continuing offending are needed.

Fourth, we asserted that the two groups would react differently to turning-point opportunities: Life-course-persistent offenders would selectively get undesirable partners and jobs and would in turn expand their repertoire into domestic abuse and workplace crime, whereas adolescence-limited offenders would get good partners and jobs and would in turn desist from crime (Moffitt, 1993, p. 695). One study showed that the potential turning point of school grade retention could prompt antisocial behavior among ordinary boys, but in contrast, retention had little effect on boys who had been on a chronic life-course-persistent tra-

jectory since childhood; the authors speculated that the chronic boys' antisocial behavior was already so ingrained that it was difficult to influence for good or for bad (Nagin, Pagani, Tremblay, & Vitaro, 2003). More such tests of the hypothesis that antisocial history moderates turning points are needed.

Fifth, we put forward a new prediction here, that the life-course-persistent antisocial individual will be at high risk in midlife for poor physical health, cardiovascular disease, and early disease morbidity and mortality (Moffitt, 2001). We based this prediction on our observation that life-course-persistent antisocial behavior is associated in adolescence with factors that are known to predict disease morbidity in midlife (Gallo & Matthews, 1999; McEwen, 2002; Repetti, Taylor, & Seeman, 2002). Such risk factors include health risk behaviors (e.g., heavy smoking, unprotected sex), high levels of stress (e.g., conflictual relationships, family dissolution, financial insecurity), and personality traits associated with physiological vulnerability (e.g., hostility, stress-reactivity, alienation). Our preliminary analyses of health indicators collected when the Dunedin study members were 26 years old has revealed that, compared to the adolescence-limited men, the life-course-persistent antisocial men already had somewhat lower high-density lipoprotein and significantly poorer tested cardiorespiratory aerobic fitness (Moffitt et al., 2005). Follow-up assessments of longitudinal studies of antisocial development should measure more physical health outcomes.

CONCLUSIONS

After 10 years of research, what can be stated with some certainty is that the hypothesized life-course-persistent antisocial individual exists, at least during the first 3 decades of life. Consensus about this group has emerged from all studies that have applied trajectory-detection analyses to a representative cohort sample having longitudinal repeated measures of antisocial behavior. Tremblay et al. (2004) detected a "high physical aggression" group constituting 14% of Canadian children followed from age 17 to 42 months. Broidy et al. (2003) detected a "chronic aggressive" group constituting 3% to 11% of children followed from age 6 to 13 years in six different cohorts from three countries. Maughan et al. (2001) detected a "stable high aggressive" group constituting 12% of North Carolina youth followed from ages 9 to 16 years. Brame et al. (2001) detected a "high chronic aggressive" group constituting 3% of Canadian youth followed from ages 6 to 17 years.

Raine et al. (2005) detected a “life-course persistent path” group that constituted 13% of Pittsburgh youth followed from ages 7 to 17 years. Fergusson et al. (2000) detected a “chronic offender” group constituting 6% of Christchurch youth followed from ages 12 to 18 years. Chung et al. (2002) detected a “chronic offender” group constituting 7% of Seattle youth followed from ages 13 to 21 years. Wiesner and Capaldi (2003) detected a “chronic high-level” group constituting 16% of Oregon youth followed from ages 12 to 24 years. Moffitt et al. (this chapter) detected a “high-persistent” group that constituted 7% of Dunedin young people followed from ages 7 to 26 years. Nagin et al. (1995) detected a “high-level chronic” group that constituted 12% of London males followed from ages 10 to 32 years. So far as we know, no research team that has looked for a persistent antisocial group has failed to find it.

A number of other postulates from the taxonomy have received modest or mixed empirical support, but overall they appear to be supported:

- Life-course-persistent antisocial behavior emerges from early neurodevelopmental and family adversity risk factors, but adolescence-limited delinquency does not.
- Genetic etiological processes contribute more to life-course-persistent than adolescence-limited antisocial development.
- Childhood-limited aggressive children, if followed to adulthood, become low-level chronic criminal offenders with personality disorders.
- Abstainers from delinquency are rare individuals who become unpopular with teen peers.
- Life-course-persistent and adolescence-limited delinquents develop different personality structures by adulthood.
- Life-course-persistent development is differentially associated with serious offending and violence in adulthood.
- Life-course-persistent antisocial development is almost exclusively male, whereas most female antisocial behavior is of the adolescence-limited type.

Some findings have received beginning support, but more research is needed:

- Adolescence-limited antisocial behavior is influenced by the maturity gap between childhood and adulthood and by social mimicry of antisocial role models.
- Childhood-onset antisocial behavior persists at least into middle adulthood, whereas adolescent-onset antisocial behavior desists in young adulthood.

Some predictions from the taxonomy have not been tested sufficiently:

- Life-course-persistent antisocial individuals will be at high risk in midlife for poor physical health, cardiovascular disease, and early disease morbidity and mortality.
- Adolescence-limited offenders must rely on peer support for crime, but life-course-persistent offenders should be willing to offend alone (although in adolescence, they serve as magnets for less expert offenders).
- Snares (such as a criminal record, incarceration, addiction, and truncated education without credentials) should explain variation in the age at desistance from crime during the adult age period, particularly among adolescence-limited offenders.
- The two groups should react differently to turning-point opportunities: Adolescence-limited offenders should get good partners and jobs that help them to desist from crime, whereas life-course-persistent offenders should selectively get undesirable partners and jobs and in turn expand their repertoire into domestic abuse and workplace crime.

It is pleasing that the taxonomy has generated interest and research. Some findings have been faithful to the hypotheses originally formulated. Other findings have pointed to important revisions needed to improve the fit between the taxonomy and nature, and some findings raise serious challenges to aspects of the taxonomy. All three kinds of findings are much appreciated. Obviously, there is still a lot of work to do.

SUMMARY 615

REFERENCES 615

Accidents, suicides, and homicides account for more than 80% of deaths in adolescence, and of these, at least half of the deaths involve drugs and alcohol (Soderstrom & Dearing-Stuck, 1993). Two-thirds of adolescents in juvenile detention facilities and nearly half of those in day and residential state programs have problems with substance abuse (Greenbaum, Prange, Friedman, & Silver, 1991), suggesting that substance abuse is at least a central, if not a primary, factor in problem behavior in adolescence. At the same time, the use of illicit drugs, especially during early adolescence, may interfere with normative cognitive, social, and emotional development, which in turn may place youths at risk for school problems and problematic peer relationships (Costello, Erkanli, & Federman, 1999; Kandel et al., 1999; Rao et al., 1999; Stacy & Newcomb, 1999; Wilens et al., 1999). Early illicit drug abuse has been linked with problem behaviors such as early sexual activity, truancy, violence, and access to weapons (Amaro,

Zuckerman, & Cabral, 1989; Brookoff, O'Brien, Cook, Thompson, & Williams, 1997). These behaviors may lead to sexually transmitted diseases and human immunodeficiency virus (HIV) infection, pregnancy, school failure, injury and accidents, homicides, and suicides (Hicks, Bemis, Bemis, & Imai, 1993).

Recent data suggest that nearly half of adolescents have tried an illicit drug at least once by the end of the 12th grade and that over three-quarters have used alcohol (Johnston, O'Malley, & Buchanan, 2001). Thus, adolescence is a critical developmental period for initiation into licit and illicit drug use and, for some individuals, the beginning of their trajectory toward substance dependence and abuse. Key questions are these: What factors predict those adolescents who will shift from licit to illicit drug use? What predicts the transition from use to dependence and abuse? What are the morbidities associated with both substance use and abuse that also impact a young person's developmental trajectory at this critical developmental period?

In this chapter, we discuss the magnitude of the problem of substance use and abuse in adolescence, risk factors for initiating substance use, including comorbid conditions, and similarly those factors that are either risky or protective for a trajectory to substance abuse. We also suggest two complementary models for these trajectories, one that

This work was supported by NIDA grants RO1-DA-06025 (LCM) and KO2-DA00222 (LCM), RO1-DA-17294 (NES), K23-DA14606 (NES), and NICHD P01-HD03008. emphasizes the pathway to use and abuse and a second that illustrates the factors leading to a transition from abuse to dependence. We conclude with a summary of possible future directions to elucidate further adolescent trajectories to substance use and dependence.

MAGNITUDE OF THE PROBLEM

Since 1975, nationwide data have been systematically collected about drug use among high school seniors (Johnston, O'Malley, & Bachman, 2001). In 1991, the annual survey was expanded to include data from 8th- and 10th graders. In 2002, more than 43,000 students in these grades in 394 schools nationwide were surveyed about lifetime, past year, past month, and daily use of drugs, alcohol, cigarettes, and smokeless tobacco. Over the 28 years that these data have been systematically collected, there have been notable fluctuations in the rates of use of licit and illicit drugs among American teenagers. For example, in 1996, use of illicit drugs among children 12 to 17 years of age had doubled from those rates reported in 1992 and was at levels comparable to those reported in the late 1970s and early 1980s, when marijuana use was reported to be as high as 1 in 2 high school students. But beginning in 1997, rates of illicit drug use among adolescents once again began to decline, and 2002 marked the 6th year in a row that illicit drug use among 8th, 10th, and 12th graders remained stable or decreased.

However, although rates of use of illicit drugs (i.e., heroin, cocaine, marijuana), alcohol, and tobacco are presently declining among adolescents, the amount of use continues to be significant. For example, in 2002 among those students surveyed, 26.7% of high school seniors, 17.7% of 10th graders, and 10.7% of 8th graders reported use of cigarettes or smokeless tobacco in the previous month; 9.1% of seniors, 4.4% of 10th graders, and 2.1% of 8th graders admitted to at least a half pack of daily use in that same period. Past month marijuana use among 12th, 10th, and 8th graders in 2002 was reported as 21.5%, 17.8%, and 8.3%, respectively. Nearly half of high school seniors (48.6%) reported using alcohol in the past 30 days; rates for 10th- and 8th graders were 35.4% and 19.6%, respectively. When any illicit drug use was examined, 25.4% of seniors, 20.4% of 10th graders, and 10.4% of 8th graders reported use at least once in the previous month. Although these prevalence rates have decreased since 1997, each is still in the same order of magnitude in that 6-year time period. Thus, illicit drug use, as well as alcohol and tobacco use, remain prevalent health problems among American adolescents. It has also been commonly reported

in studies of teenage substance abuse that specific substances are rarely used exclusively but that polydrug use is quite common (Clayton & Ritter, 1985). In the more recent phases of the Monitoring the Future Study, systematic data were collected regarding adolescents' perceptions of the perceived risks of drug use and the availability of drugs. For many illicit drugs, adolescents' perceived risk of drug use decreased between 2001 and 2003, suggesting that 8th- to 12th graders are less cautious about illicit drug use.

Gender and ethnic differences among adolescent drug users are also notable in the yearly survey data (Johnston, O'Malley, & Bachman, 2003; Wallace et al., 2003). Over the years covered by the survey, the gender gap in use of illicit drugs, alcohol, and/or tobacco has remained largely unchanged. Males have higher rates of illicit drug use, particularly higher rates of frequent use, and higher rates of marijuana and alcohol use. However, girls are as likely as boys to report being daily smokers. These gender differences tend to appear more as children get older. Ethnic differences in drug use, for boys as well as girls, are much wider than are gender differences. Contrary to popular assumption, African American boys and girls tend to have substantially lower rates of illicit and licit drug use than Whites. Cigarette use is especially lower for African Americans. Native American teenagers are most likely to smoke daily and African Americans least likely. Similar patterns are found for heavy alcohol use (five or more drinks in a row within the past 2 weeks) and for marijuana, though African American boys are much more likely to use marijuana compared to African American girls. Hispanics have rates of use that fall between White and African American youths, though usually closer to the rates for Whites than for Blacks. Hispanics do have the highest reported rates of use for some drugs in 12th grade—crack, heroin with a needle, and ice—and their level of heroin, cocaine, methamphetamine, and steroid use is roughly equivalent to that of Whites. But in 8th grade, Hispanics tend to use the most of any class of drugs. One possible reason for this change in Hispanic drug use between the 8th and 12th grade may be because of the higher rates of school dropout of Hispanic youth. Thus, more of those Hispanic adolescents who are drug using or drug-prone leave school before the 12th grade compared to White and African American children.

Differences in overall illicit drug use associated with population density are not very large or consistent over the years of the survey (Johnston et al., 2003). Drug use is a widespread phenomenon among American youth from both urban and rural settings. In surveys from recent years, the use of a number of licit and illicit drugs has actually declined in some urban areas relative to nonurban areas; in

contrast to popular belief, crack cocaine and heroin use among adolescents or adults is not concentrated in urban areas. Similarly contrary to commonly held assumptions is the finding that for many drugs, differences in use by socioeconomic class are very small; in general, trends for patterns of use have been similar across social classes. Patterns of distribution and availability of drugs surely influence differences by socioeconomic class. For example, in the early 1980s, cocaine use was more prevalent among higher socioeconomic classes, but with the appearance of crack, a cheaper form of cocaine, that difference disappeared by the mid- to late 1980s. Cigarette smoking has shown a similar homogenization across socioeconomic classes as students from poorer families have stopped smoking or not begun use in recent years with the increasing overall negative publicity associated with tobacco use. Nonetheless, even with these shifts, there still remains a slightly greater use of tobacco among students from poorer, less educated families.

Early use of some drugs may predict later involvement in illicit drug use (Lynskey, Coffey, Degenhardt, Carlin, & Patton, 2003; Wagner & Anthony, 2001; Wilcox, Wagner, & Anthony, 2002). The so-called gateway theory of adolescent drug use suggests that drugs such as tobacco and alcohol are entry-level drugs for later use of marijuana and other illegal drugs such as cocaine and hallucinogens. Similarly, marijuana is regarded by several as the gateway drug for illicit drug use (Fergusson & Horwood, 2000; Yamaguchi & Kandel, 1984). Drugs such as tobacco, alcohol, and marijuana may serve as gateways to other drug use because they provide opportunities for users to obtain other drugs; perhaps some users actively seek out these opportunities, whereas others are more passive recipients of drug exposure opportunities (Wagner & Anthony, 2002).

Using annual survey data from the 1991 through 1994 National Household Survey on Drug Abuse, investigators analyzed the responses of 26,015 individuals ages 12 to 18 regarding marijuana use and the responses of 44,624 individuals ages 12 to 25 who answered questions regarding cocaine use (Wilcox et al., 2002). Alcohol and tobacco users were more likely than nonusers to try marijuana when the opportunity arose. About 75% of alcohol or tobacco users reported an opportunity to try marijuana by age 18, and more than 85% of them made the transition to marijuana use. Conversely, only 25% of nonsmokers and nondrinkers were given an opportunity to try marijuana by the same age, and of these, fewer than 25% began smoking marijuana within 6 years after they were first given the opportunity. Overall, alcohol or tobacco users were 7 times more likely to start using marijuana than individuals who had

used neither alcohol nor tobacco. Previous marijuana use was also associated with the opportunity to try cocaine and the likelihood of an adolescent's starting to use cocaine once given the opportunity. Among the youth who were given the chance to try cocaine, those who were already using marijuana were 15 times more likely to use cocaine than those who did not use marijuana. About 50% of marijuana users tried cocaine within 2 years of their first opportunity to do so. However, among young people who never used marijuana, fewer than 10% initiated cocaine use. Although males are more likely than females to have opportunities to use drugs at any age, both are equally likely to make a transition into drug use once an opportunity to try a drug has occurred.

Early drug use not only affords adolescents more exposure to other drugs, but the early user is more likely to take advantage of these opportunities to try other drugs. And among those users, a proportion will go on to drug dependence. For example, data from the National Comorbidity Study conducted between 1990 and 1992 with detailed interviews with more than 8,000 women and men ages 15 to 54 showed that first use of marijuana occurs on average at age 18, and on average, 9% of users will become dependent on the drug, most likely before age 25 (Anthony, Warner, & Kessler, 1994). For cocaine, first use is most likely around age 20, and progression to dependence is more rapid; the peak incidence of transition to dependence occurs between ages 23 and 25 for on average 21% of individuals who have used cocaine at least once. Not only is early use of alcohol or tobacco associated with more opportunities for trying marijuana or cocaine, but early use of these drugs may set in motion a pathway to early illicit drug dependence for a significant proportion of adolescents and young adults (Anthony et al., 1994). And once an adolescent develops a substance abuse problem, he or she is also very likely to suffer other medical and mental health problems. Data from the Drug Abuse Treatment Outcome Study for Adolescents, a multisite longitudinal study of adolescents in residential, outpatient, and inpatient treatment, reported that 64% of the sample had at least one comorbid mental disorder, most often Conduct Disorder. Adolescents who had accompanying mental health problems also had more problems with family, school, and criminal involvement (Grella, Hser, Joshi, & Rounds-Bryant, 2001). Jainchill and colleagues (Jainchill, De Leon, & Yagelka, 1997) report high rates of psychiatric comorbid conditions in a sample of 829 adolescents entering residential placements; more than 90% of the sample had a psychiatric diagnosis other than their substance use disorder (primarily Conduct Disorder and Oppositional Defiant Disorder).

It is important to note one potential flaw in the yearly survey data from the National Institute on Drug Abuse (NIDA) sponsored Monitoring the Future Study (Johnston, O'Malley, & Bachman, 2001). This study is based solely on students in middle and high school. Many severely substance abusing adolescents may already have dropped out of high school sometime between the 8th and 12th grade, as was suggested for the apparent decline in Hispanic drug use by late high school. These more severely drug-using adolescents are then not included in the survey data, with the result that the problem is underestimated and prevalence estimates from the survey population data may not be adequately reflective of more clinical populations that present for treatment and/or other health or psychosocial difficulties in their late teens and early 20s.

Despite this caveat, the survey data do describe several important trends. These data, accumulated from many years, suggest that licit and illicit drug use begins in early adolescence for a significant number of children even though the rates are apparently slowly declining. Children are susceptible across socioeconomic class, gender, cities and community size, and population density. Those who begin early tend to continue, and the rate of beginning use increases through high school. Those adolescents who are already using licit drugs by the time they graduate high school are more likely to continue their drug use, to begin illicit drug use, and to become involved in other problem behaviors. The factors explaining these trajectories are multivariate and interactive. Key to understanding the developmental trajectory of substance use is identifying which factors tip the balance between use and dependence, with the attendant social, physical, and psychiatric comorbidity associated with drug addiction. We turn now to the various risk factors that appear to increase an adolescent's likelihood of beginning and sustaining drug use and the factors that contribute to the development of drug dependence among a proportion of drug users.

RISK FACTORS

Risk factors are those conditions that are associated with a greater likelihood of negative outcomes, such as substance use and abuse. Recent perspectives conceptualize substance abuse as a developmental disorder with genetic, neurobiological, and environmental determinants (Riggs & Whitmore, 1999). Many factors contribute to the risk for developing substance abuse or dependence. Newcomb (1995, 1997) descriptively divides risk factors for sub-

stance abuse into four domains: cultural and societal, interpersonal, psychobehavioral, and biogenetic. (In this taxonomy, psychiatric comorbidity is included under psychobehavioral risks.) In a more functional taxonomy, Pandina (1996) suggests that risk factors for substance abuse may be grouped into three categories: markers or surface indicators, modifiers that either increase or decrease the relative risks, and mediators or causal mechanisms. Cicchetti and Rogosch (1999) divide markers into those that are fixed, such as gender or a perinatal event such as prematurity, and those that are variable, such as the availability of drugs or use among peers. However classified, clearly, no one risk factor is causal and no one factor is completely protective. Generally, the more risk factors one has, the greater the risk of developing the disorder, or more specifically, the greater the risk of substance abuse and possibly dependence. And different combinations of risk factors lead to different potentials for negative outcomes based on the strength and nature of the individual factors. Multiple individual and experiential conditions combine to form multiple pathways or trajectories to substance use and abuse (Fergusson, 1998). At the same time, some factors may cushion the impact of a risk factor and may modify the severity of or prevent a negative outcome. Indeed, a number of investigators have begun to study the interaction between risk and protective factors on the trajectory toward substance abuse (Newcomb, 1995; Pandina, Johnson, & Labouvie, 1992).

Specific risk factors have greater impact at certain developmental stages compared to others (Newcomb, 1995). For example, using Newcomb's (1995, 1997) descriptive categories, societal and cultural risk factors such as drug availability and societal norms favorable to drug use have an impact throughout all developmental stages, but interpersonal factors, including parental care, family disruption, and peer relations, may be developmentally most critical for children and adolescents. Biogenetic risk factors, including psychophysiological vulnerability to drug effects, may be most critical in the transition from drug use to drug dependence. We first discuss these risk factors in these descriptive groupings and then provide a more functional analysis of those that serve as fixed or variable markers, those that appear most often to serve as moderators, and those that may serve a mediating role.

Societal and Cultural Factors

Cultural and societal factors include living in a community where one can procure drugs with ease and where laws and

norms more readily permit or do not strongly discourage a drug culture (Newcomb, 1995). For the United States, the National Household Survey on Drug Abuse (P. B. Johnson & Richter, 2002; U.S. Department of Health and Human Services, 1999) reported that over 50% of teenagers between the ages of 12 and 17 believed marijuana to be easily obtainable, and 35% had been offered the drug. When marijuana was easy to obtain, the percentage of White adolescents who had used the drug within the past 12 months was 26%; however, only 2% used the drug when they found it hard to obtain. Availability issues may also be impacted by living in a poorly organized and highly dense neighborhood in which there are more concentrated rates of criminal activity and drugs are a central part of the neighborhood economy. Although, as already cited, minority ethnic status and poverty are not necessarily more often associated with beginning substance use, these same factors moderate individual adolescents' trajectory toward dependence after they have initiated use (Fergusson, 1998; Hawkins, Catalano, & Miller, 1992; Riggs & Whitmore, 1999).

Interpersonal Factors

Interpersonal factors include those that describe parental behavior with the child, parental psychopathology (which in turn influences parental behavior), parental attitudes toward substance abuse, family dynamics, and the presence of abuse. For older children, peer relationships become as influential as parents and families in exposing children to opportunities for drug use. Among the parental factors implicated to increase the risk of adolescent substance use are how strongly parents believe drugs are harmful and how much parents actively monitor their children and/or are involved in their children's activities (Chilcoat & Anthony, 1996; Duncan, Biglan, & Ary, 1998; J. L. Johnson & Leff, 1999; Molina, Chassin, & Curran, 1994). Parents who have lower academic aspirations or, more generally, convey less of a sense of optimism and a future for their children may also increase the risk for their children's entry into early substance use and/or into less socially integrated peer groups that are more likely to use drugs (Brook, Linkoff, & Whiteman, 1980). Family abuse, including domestic violence, family disruption, negative communication patterns, and lack of anger control, are also often reported as characteristics of the families of substance-using adolescents and young adults (Baumrind, 1983; Reilly, 1979). These latter family characteristics appear to increase the risk of substance use in the child whether or not the parents are actively using drugs (Bennett & Kempfer, 1994).

How much parents attend to their younger children's activities, their friends, and specifically their opportunities for substance use has a strong impact on preadolescents' beginning drug use. Rates of illicit drug use such as cocaine or marijuana are higher among middle school children who report less parental concern and involvement in their lives (Chilcoat & Anthony, 1996). Parental use of licit drugs such as tobacco or alcohol models an acceptance of drug use that increases the likelihood of young children trying these drugs. Not only are their children more likely to try tobacco or alcohol, but the impact of perceived parental acceptance increases the likelihood of continued use (Jackson, Henriksen, Dickinson, Messer, & Robertson, 1998).

A range of peer factors have been cited as putting a child at risk for substance use, including affiliation with a deviant and substance-abusing peer group and affiliation with peers who have low adherence to conventional societal norms (Fergusson, 1998; Hawkins et al., 1992; O'Donnell, Schwab-Stone, & Muey, 2002; Riggs & Whitmore, 1999). Peer influence has been consistently regarded as the strongest predictor for substance use among adolescents (Oxford, Harachi, Catalano, & Abbott, 2000). Peer attitudes about the use of substances predict the initiation of alcohol and other substance use (Bauman & Ennett, 1994). Indeed, by adolescence, peer attachments may be stronger than family attachments in predicting susceptibility to substance use (Brook et al., 1980). O'Donnell and colleagues evaluated the extent to which family, school, and peer support factors contributed to two different dimensions: (1) mental health problems such as depression, anxiety, and somatization, and (2) conduct problems such as drug abuse, delinquency, and school misconduct, in children with various levels of community violence exposure. The participants in this study were divided into three groups: a victim group, a witness group, and a no-exposure group. Among all three groups, peers served as a negative influence on resilience in terms of substance abuse and school misconduct, particularly for the victim group.

Friedman and Glassman (2000) found that association with a delinquent peer group was the strongest predictor for later substance use in childhood and adolescence. The percentage of children who tried marijuana rose sharply for those whose friends would not be upset at all if they tried marijuana versus those who would be upset (i.e., 44% versus 2%). In turn, children who experience school failure and emotional distress may be more prone to affiliate with deviant peers, thus increasing their risk of future substance use (Ingram & Price, 2001). The low adherence to societal norms is illustrated in early sexual involvement by males,

which predicted drug use (Newcomb, 1995). In addition, a negative social environment, including peer rejection, may increase an adolescent's sense of isolation and risk of future substance use (Hawkins et al., 1992). Peer influence also plays a role in predicting relapse after substance abuse treatment. For example, one study showed that 90% of the adolescents who had a relapse attributed their returning to drugs to peer pressure (Brown, 1993).

Psychobehavioral Factors

These factors include children's age, degree of academic success or failure, motivation for learning, the presence of early and persistent behavioral problems, and poor impulse control or inability to delay gratification. Children who begin drinking at an early age (11 or 12 years) are much more likely to develop a substance abuse disorder in their teens or early adulthood compared even with those who delay their use of alcohol until later in high school. Those who begin drinking at age 19 or 20 years have much lower rates of later substance use (<2%; DeWitt, Adlaf, Offord, & Ogborne, 2000). The progression to substance abuse disorders appears more related to the age of initiation and the frequency rather than the duration of use (DeWitt et al., 2000; Kandel et al., 1999). Those individuals with early-onset use have a shorter time from first use to dependence than do groups with later use and adult-onset addictive disorders (Clark, Kirisci, & Tarter, 1998). Beginning alcohol use at an early age is also associated with a greater likelihood to use other substances, including illicit drugs. Adults who began their alcohol use in adolescence have higher lifetime rates of marijuana and other illicit drug use and higher rates of depression and disruptive behavior problems (Clark et al., 1998).

The school environment is an important context in which risk factors may be identified. Level of academic success and behavior in the school setting can be powerful predictors of later substance use. Educational factors that have been shown to be associated with substance use include low IQ, poor academic achievement, specific learning disabilities, disruptive behavior/conduct problems and truancy, and poor social skills (Fergusson, 1998; Scheier, Botvin, Diaz, & Griffin, 1999; Stacy, Newcomb, & Bentler, 1993). School failure has been shown to increase the likelihood that a child will use drugs, with some reports indicating failure at the elementary school level and others pinpointing academic difficulties in later grades (Hawkins et al., 1992; Haynes, Troutman, & Nwachuku, 1998). Similarly, a low degree of commitment to school has been linked to an adolescent's greater likelihood of beginning

drug use (Hawkins et al., 1992). Wallace and Muroff (2002) found that African American children are more exposed to contextual risk factors, such as economic deprivation and academic failure, and White children are more exposed to individual and interpersonal risk factors, such as sensation seeking and peer use. Both factors may contribute to the adolescent's beginning drug use, but the trajectories may be different for children from different ethnic groups.

Other psychological characteristics may influence which adolescents continue their substance use and develop dependence disorders as young adults and which do not. Indeed, although early use is a strong predictor for continued and more severe use, there are nonetheless adolescents who begin their use early and who do not go on to develop substance abuse disorders (Hasin, Grant, & Endicott, 1990). Longitudinal studies of, for example, early alcohol use suggest that young adults who continue to be problem drinkers are more likely to have been rebellious, nonconformist, deviant, or isolated during high school (Newcomb, 1997). Temperament dimensions have been related to substance use in early adolescence and to addiction and behavior problems by early adulthood (Caspi, Henry, McGee, Moffitt, & Silva, 1995; Masse & Tremblay, 1997; Pulkkinen & Pirkkanen, 1994; Wills, DuHummel, & Vaccaro, 1995). Individual traits such as sensation seeking, low harm avoidance, poor impulse control, and negative emotionality are personality factors associated with later substance use (Colder & Chassin, 1997; Hawkins et al., 1992; Wills, Sandy, Shinar, & Yaeger, 1999). Kubicka and colleagues (Kubicka, Matejcek, Dytrych, & Roth, 2001) found that novelty seeking and low harm avoidance characteristics predicted substance use in 15-year-olds. They also found a possible link between childhood extraversion and later alcohol use and smoking. In a study of 508 adolescents, personality-related risk factors for substance abuse were associated with using substances for coping and conformity (Comeau, Stewart, & Loba, 2001). Admitting that affective states may have a general role in substance abuse, Wills et al. hypothesized that high levels of positive affect might reduce substance use and operate as a buffering agent. They conducted a longitudinal study in which they followed 1,699 students from 7th to 10th grade for 4 years. The results showed that positive and negative affect showed independent contributions to substance use: Negative affect was related to increased substance use, and positive affect was inversely related to change in substance use. The relationship between internalizing disorders, their temperamental substrates, and risk for substance use is an important line of study (Price

& Lento, 2001), especially in the consideration of those factors that reduce the risk between exposure to opportunities for drug use and substance abuse.

Psychiatric Comorbidity

Psychiatric disorders influence substance use and abuse throughout life, and there is a considerable literature on psychiatric comorbidity. Rates of mood and disruptive disorders are higher in adolescents with substance abuse problems than in those without. Rates of comorbidity of substance abuse with other psychiatric disorders are the same in adolescents as in adults, except for Disruptive and Antisocial Personality Disorders, higher rates for which are found in adults. Adolescents who relapse after drug treatment programs are also more likely to have comorbid psychiatric disorders (Kaminer & Burleson, 1999).

Among populations of adolescents referred for substance abuse treatment, Conduct Disorder, Major Depression, and Attention Deficit Disorder are the most common concomitants of substance dependence (Jaycox, Morral, & Juvonen, 2003). In young women, depression is more often the usual comorbid disorder (Whitmore et al., 1997); also commonly associated with substance abuse disorder in women in Posttraumatic Stress Disorder, usually with depression (Clark et al., 1997). Studies examining the predictors of comorbid substance abuse in depressed adolescents referred for treatment document longer depression episodes, more conduct problems and general psychosocial impairment and isolation, and more school and/or work problems (King et al., 1996).

Depression

Depression occurs in approximately 20% of adolescents (Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993) and substance use disorders in 25% of depressed adolescents (Fleming & Offord, 1990). Risk factors common to both depression and substance use in adolescents include poor coping skills, interpersonal conflict with parents, poor academic achievement, and low academic motivation (Lewinsohn, Gotlib, & Seeley, 1995). Therefore, those children and adolescents experiencing depression, attentional problems, or Conduct Disorder have an elevated risk for substance abuse (Deykin, Buka, & Zeena, 1992).

The combination of depression and substance abuse is particularly problematic in young girls. Usually, Major Depression is associated with a more severe level of substance dependence. Conversely, depression in adolescence also raises the risk of more severe substance use and a rapid

entry into dependence (Riggs, Baker, Mikulich, Young, & Crowley, 1995). In a study comparing depressed adolescents without prior substance abuse histories to nondepressed controls, the rate of substance use was high in both groups but higher in the depressed group (34.6% in the depressed group and 24.1% in the controls). Depressed girls who were abusing drugs were more psychosocially impaired, had more anxiety traits, and had dysregulated circadian fluctuations in cortisol compared to depressed girls who were not abusing drugs. Also, those girls who were both depressed and substance abusing had an earlier onset of their substance use compared to nondepressed girls who were using drugs (Rao et al., 1999). Each of these associations suggests that depression in adolescents, particularly in girls, marks a high-risk time for their beginning substance use and a critical point for intervention focused as much on the risk of drug use as on their depression.

For boys, depression also plays a significant role but with a slightly different profile marked by more difficulties with conduct and attentional problems. Depressed boys who are also abusing substances are more likely to have Posttraumatic Stress Disorder, anxiety disorders, and Attention-Deficit/Hyperactivity Disorder (ADHD; Riggs et al., 1995). Conduct Disorder and depression increase the risk of an earlier onset of substance dependence. But is the comorbidity between Conduct Disorder and substance abuse more a reflection of the impact of a number of illicit drugs on behavior? In other words, what is the risk to develop Conduct Disorder independent of substance dependence? Although this has not been studied directly, one study examined the relationship between adolescent-onset Bipolar Disorder and substance abuse and found that adolescents with Bipolar Disorder had over 8 times greater risk to develop substance dependence compared to those with child-onset Bipolar Disorder. Conduct Disorder did not account for this elevated risk, suggesting that substance dependence and conduct problems are not entirely overlapping (Wilens et al., 1999; see also next paragraphs).

The risk of suicide is elevated among adolescents and young adults who are substance abusers. For example, post-mortem case reviews of adolescents who committed suicide have found that 70% were drug and alcohol users (Shafii et al., 1988). Among adolescents who actually commit suicide, a much greater proportion were using alcohol at the time of their death (Brent et al., 1993). Multiple risks involving substance use appear to converge for suicide victims. These include active substance dependence with Major Depression, a family history of depression and substance use, and the ready availability of firearms in the home (Brent, Perper, & Allman, 1987; Bukstein et al.,

1993). Indeed, White boys who are intoxicated are much more likely to commit suicide using a firearm if one is readily available (Kaminer, 1992). Persistently high levels of problem drinking and/or other substance use and depressive symptoms are also associated with high levels of suicidal thoughts and attempts, and the longer the duration of suicidal thoughts along with substance dependence, the higher the likelihood of suicide (Deykin & Baka, 1994).

Conduct Disorder

The presence of Conduct Disorder before the development of substance abuse seems to carry a poorer prognosis for the adolescent than for those who develop their conduct problems concomitant with their substance abuse (Myers, Stewart, & Brown, 1998). Conduct problems comorbid with attentional regulatory difficulties also presage a higher risk for involvement with drugs. Adolescents with ADHD and Conduct Disorder are at a higher risk of developing substance abuse problems than those with ADHD alone (Wilens, Biederman, & Spencer, 1996). A prospective study longitudinally followed for 8 years children with ADHD and children with ADHD plus Conduct Disorder. Those with both ADHD and Conduct Disorder used as much as 5 times more alcohol and cigarettes than those with ADHD alone (Barkley, Fischer, Edelbrock, & Smallish, 1990). Another study examined 626 pairs of 17-year-old twins. Once again, ADHD alone did not increase the risk for substance abuse unless there were also concomitant conduct problems (Disney, Elkins, McGue, & Iacono, 1997).

There are apparent differences in the presentations of girls and boys who have conduct problems along with their substance dependence. Boys are more likely to have aggressive symptoms, including stealing, destruction of property, cruelty to animals, fighting with weapons, and criminal activity such as breaking and entering. The severity of the aggression and the presence of ADHD and depression predict an earlier and more severe onset of substance dependence in boys; in girls, only Major Depression seems to predict earlier and more severe substance abuse (Riggs et al., 1995). Girls with conduct problems and substance abuse are more likely to have a diagnosis of nicotine dependence, to start drinking at a later age and to have more running away behavior compared to boys, and to be involved in less criminal or aggressive activity (Mezzich et al., 1994).

Later-onset conduct problems (in late adolescence) not associated with ADHD are also associated with increased risk for substance dependence. Grillo and colleagues (Grillo et al., 1996) suggest that later-onset conduct problems are a form of personality dysfunction and are more

likely to be accompanied by substance abuse than are early-onset ADHD and conduct problems, which may reflect neurobehavioral difficulties secondary to ADHD. Another insight into this distinction comes from studies with juvenile offenders (Randall, Henggeler, Pickrel, & Brondino, 1999). Substance-abusing juvenile offenders with externalizing disorders and high rates of antisocial behavior had a much worse trajectory as studied for 16 months than those juvenile offenders who were only substance abusing or those who also had internalizing disorders. It may be that internalizing symptoms such as anxiety buffer the more deleterious and destructive effects of conduct problems comorbid with substance abuse.

Anxiety Disorders

Children who suffer from anxiety with or without antisocial personality characteristics coupled with chronically stressful living environments may have greater risk for later substance use (Newcomb, 1995). Like other disorders already mentioned, it appears that the onset of anxiety disorders usually precedes the onset of substance use and abuse, a finding that has been replicated across cultures (Merikangas et al., 1998). The most common type of anxiety disorder that is apparently associated with substance abuse is Posttraumatic Stress Disorder (Clark et al., 1995), especially for children who have grown up exposed to chronic stress and parental abuse and/or neglect.

Another form of anxiety that may play a role in the development of substance dependence is Social Phobia. In a study of 1,035 adolescents 13 to 17 years of age, Social Phobia was highly comorbid with depression and substance abuse (Essau, Conradt, & Peterman, 1999). Another study showed that Social Phobia and Agoraphobia seemed to precede the onset of alcohol abuse, whereas more generalized anxiety or panic disorders did not (Kushner, Sher, & Erickson, 1999). Other long-term studies have shown that anxiety manifest as shyness coupled with aggressiveness in adolescents were strong predictors over 2 decades later of cocaine abuse in adults (Swan, 1995).

Methodological Caveats

Each of these associations raises another question regarding comorbidity of depression, Conduct Disorder, anxiety, or other disorders with substance abuse problems: Do these comorbid disorders usually precede the development of substance abuse problems, or are they more likely to follow the initiation of heavy drug use? Costello and colleagues (1999) showed that ADHD, Conduct Disorder, Oppositional Defiant Disorder, and anxiety disorders seemed to occur long before the onset of actual substance dependence

(though not as clearly before the initiation of substance use). However, depressive symptoms seemed to occur at least 1 year after the onset of alcohol abuse but 2 years before the onset of smoking. In the case of both depression and disruptive disorders, the rates and age of onset of substance dependence were significantly higher and earlier than in youths without comorbid mood or conduct problems. A study examining hospitalized adolescent substance abusers showed that for at least half, their Dysthymia had preceded the development of their substance dependence (Hovens, Cantwell, & Kiriakos, 1994). A study of adolescents with Dysthymia and problem behavior showed that moderate to heavy alcohol consumption appeared to follow the earlier psychiatric and behavioral history (King, Naylor, Hill, Shaina, & Gredena, 1993).

A second major methodological issue plaguing each of these studies is that the majority of the work on comorbidity and substance abuse utilizes clinically referred samples, that is, adolescents who are sufficiently ill to be referred for treatment by physicians, family, child welfare, or the legal system. Thus, the clinical correlates, the comorbid disorders, may actually be correlates of the referral population regardless of whether or not the comorbid disorders appear before or after the substance abuse (Angold, Costello, & Erkanli, 1999). Longitudinal methods of large population-based samples such as those accomplished by Newcomb and colleagues (Newcomb, 1995, 1997; Newcomb & Bentler, 1988b) are the best solution to this problem, but there are very few of these studies in the literature.

A third methodological issue is the overlapping symptoms among the various diagnostic categories. Poor impulse control may be a feature of ADHD, conduct problems, and substance dependence. Dysphoria may be a result of chronic drug use. Indeed, even some of the stimulants such as cocaine are associated with profound lows following the highs, especially after chronic use. Thus, some of the symptoms characteristic of certain comorbid disorders may be both exacerbated by substance use and mimicked by the effects of the drugs.

Each of these methodological issues illustrates the complexity of this area of work in adolescent substance abuse and the need for research designs that creatively attempt to tease apart overlapping symptoms and disorders.

Biological and Genetic Factors

A considerable literature has developed about the generational transmission of substance abuse, particularly alcoholism. In a large epidemiological survey, 8,865 secondary

school students were asked about their own and their parents' use of drugs and alcohol (Smart & Fejer, 1972). For all 12 drugs (including alcohol) that students were asked about, there was high agreement between students' and parents' use of drugs, and the specific drug was often concordant. The strongest relationship in parent-child use was maternal and children's use of tranquilizers. Annis (1974) studied 539 adolescents and their families and found a significant relationship between parents' and adolescents' use of alcohol, with similar patterns of use grouping within mother-daughter and father-son pairs. In a study using child and separate mother and father interviews (Fawzy, Coombs, & Gerber, 1983), teenagers were significantly more likely to use drugs or alcohol if their parents were users or if the teenager perceived the parent to be a user. For example, of the parents reported by the teenager to be a marijuana user, 81% of fathers and 78% of mothers had substance-abusing adolescents. Similarly, if parents reported themselves to have at least one drink of beer or wine per day, 72% of fathers and 77% of mothers were likely to have a substance-abusing teenage.

Each of these studies raises the question of how drug use is transmitted across generations and what are the genetic as well as environmental contributions to the notable concordance in parental and child drug use (Deren, 1986). More recent findings suggest that the multigenerational transmission patterns of substance abuse may be mediated by gender. Among families of addicts, higher rates of alcoholism have been found in fathers as compared with mothers; conversely, higher rates of affective disorders are found in mothers (Mirin, Weiss, Griffin, & Michael, 1991). In a sample of adolescents in treatment, the extent of drug use by the child related to the extent of alcohol use by the father but related more strongly to the use of drugs, not alcohol, by the mother (Friedman & Utada, 1992).

Until recently, few studies have moved beyond the correlational design to examine other factors, such as socioeconomic status and parental psychological and psychiatric characteristics, that may contribute to the parental substance abuse and compound the genetic risk for the children. For example, among substance abusers' parents and siblings, there is a high rate of psychiatric disorders such as depression and Antisocial Personality Disorder that are also comorbid with substance abuse (Mirin et al., 1991; Rounsaville et al., 1991). In a study of 492 parents and 673 siblings of cocaine abusers and 400 parents and 476 siblings of opiate abusers (Luthar, Merikangas, & Rounsaville, 1993), several variables, including gender and psychiatric status of the parent, ethnicity, and type of drug abused, seemed to mediate the relationship between

parental and child drug use. Maternal depression was associated with both depression and drug use in the adult offspring. Similarly, paternal alcoholism was significantly associated with alcoholism or drug abuse in adult offspring, but only for African American and not Caucasian families.

It may be that genes play a role in an individual's individual susceptibility to dependence once a person begins to experiment with drugs, usually during adolescence or young adulthood. In other words, the inherited vulnerability may be a psychophysiological susceptibility to the addictive effects of drugs (McGue, Elkins, & Iacono, 2000; Newcomb, 1995). Indeed, in contrast to the gateway model mentioned earlier that suggests certain drugs such as marijuana serve as a gateway or stepping stone to greater illicit drug use (Fergusson & Horwood, 2000; Yamaguchi & Kandel, 1984), there is an emerging literature suggesting that marijuana and other illicit drug use is moderately heritable (Morral, McCaffrey, & Paddock, 2002). Twin studies have estimated that 30% to 60% of the variance in marijuana use in adolescence (Kendler, Karkowski, Neale, & Prescott, 2000; Kendler et al., 2002; Kendler & Prescott, 1998a; Lynskey et al., 2002) and 45% to 62% of the variance in marijuana dependence can be attributed to heritable factors (Kendler & Prescott, 1998a, 1998b; Lynskey et al., 2002). Similar estimates are made for the heritability of other illicit drug use and drug dependence (True et al., 1999; Tsuang et al., 1998).

In the mature brain exposed repeatedly to cocaine (and other drugs of abuse), neuronal functions gradually change (e.g., tolerance), and these changes may endure even after cessation of drug use. Such delayed, gradually developing, and persistent changes in function suggest that a candidate mechanism for addictive phenomena may be long-term changes in neuronal gene expression (Nestler, Bergson, Gultart, & Hope, 1993). In the mature brain, genes regulate the synthesis of neuropeptides, monoamines, their receptors, second messengers, and more. (Second messenger systems are those chemical events within a cell that are generated in response to the binding of a hormone or neurotransmitter to their receptor on the surface of the cell. The second messengers, including G proteins, then trigger a series of molecular interactions that alter the physiologic state of the cell.)

The expression of specific genes in the central nervous system appears regulated by a class of DNA-binding proteins termed transcription factors. These transcription factors bind to the regulatory regions of certain genes and affect the rate at which these genes are transcribed (and thus the synthesis of the relevant synaptic components). These transcription factors, called as a group "immediate

early genes" (IEGs; Sheng & Greenberg, 1990), appear rapidly (within minutes) in response to neuronal stimulation. The messenger RNAs (mRNAs) transcribed from IEGs often have a very short half-life; that is, the induction of these genes is short-lived. For example, the IEG c-Fos can be undetectable within a half-hour of stimulus induction (Sheng & Greenberg, 1990). For the induction of c-Fos, c-Jun, and Zif268 in response to novel stimulation, mRNA transcription occurs within 5 minutes, with peak steady-state levels of mRNA at 30 to 45 minutes and peak protein synthesis within 2 hours of stimulation (Kosofsky & Hyman, 1993). IEGs may activate or repress the rate at which other genes are transcribed, though the mechanism for this regulation of transcription rate is not yet clear (Plashne & Gann, 1990). The transient nature of the mRNA from induction of IEGs suggests a complicated stimulus-dependent mechanism for regulating such events as the synthesis of receptors and transporters. The IEG response can also be used as a marker of neuronal activation (Sheng & Greenberg, 1990).

Drugs of abuse affect the expression of IEGs in the mature and the developing animal, and the effect is apparent during and after treatment. This relationship may be one mechanism to explain how substances of abuse alter genetic programs in the different phases of neural ontogeny in both early development and during puberty, as with the vulnerable adolescent. That is, drug-induced alterations in IEG expression can modify neural gene expression during development and thereby alter, perhaps permanently, cellular identity and the neuronal repertoire (Kosofsky & Hyman, 1993). In the adult animal, exposure to cocaine enhances the expression of several IEGs, including c-Fos and Zif268, as well as genes encoding for neuropeptides such as substance P and dynorphin involved in the predominantly striatonigral dopaminergic pathways (Steiner & Gerfen, 1993, 1995) that are critical to reward pathways in the brain. Similar induction of these same IEGs is seen with agents that stimulate the dopamine D₁ system (Robertson, Vincent, & Fibiger, 1992). The cocaine-related induction can be blocked with D₁ antagonists (Steiner & Gerfen, 1995) and does not occur in a D₁-deficient mouse (Drago, Gerfen, Westphal, & Steiner, 1996; Moratella, Xu, Tonegawa, & Graybiel, 1996). Similarly, with chronic exposure, there may be long-term perturbations in IEG expression. For example, during withdrawal from cocaine treatment, adult rats showed reduction in c-Fos expression for several days (Ennulat, Babb, & Cohen, 1994).

Thus, it may be that social circumstances facilitate opportunities for initial experimentation with illicit drugs but that genetic factors play a significant role in how individu-

als move beyond that initial experimentation. Those who have a greater genetic predisposition to become dependent or substance abusing may be more susceptible to the effects of, for example, alcohol on gene expression, a model developed in detail by Nestler and colleagues (Nestler, Bergson, Gultart, & Hope, 1993; Nestler, Gao, & Tamminga, 1997; Nestler, Hope, & Widnell, 1993). In this model, continued exposure of specific subcortical regions of the brain (e.g., ventral tegmentum and nucleus accumbens) permanently changes second messenger systems within the cell, which in turn influences the function of immediate early genes and salience reward mechanisms central to the response to the drug.

Polymorphisms of the dopamine D₂ receptor (D₂(A1) allele) have been associated with addictive behaviors, substance abuse generally, and cocaine and/or alcohol abuse specifically (Berrettini & Persico, 1996; Comings et al., 1991; Compton, Anglin, Khalsa-Denison, & Paredes, 1996; George, Cheng, Nguyen, Israel, & O'Dowd, 1993; Goldman, Urbanek, Guenther, Robin, & Long, 1997; Noble, 1993; Noble et al., 1993; Smith et al., 1992; Uhl, Persico, & Smith, 1992). Similarly, polymorphisms of the dopamine transporter gene have been associated with cocaine-induced paranoia in Caucasian substance abusers (Gelernter, Kranzler, Satel, & Rao, 1994). The functional significance of these polymorphisms is not known, and many studies suggesting a genetic hypothesis for substance abuse are flawed by heterogeneous samples. It is highly unlikely that substance abuse is a monogenic disorder; it is more likely that these particular (and/or other) alleles may work in concert with other genes and environmental contexts to convey increased risk for substance abuse in a *certain proportion* of substance users. This possibly increased genetic risk is particularly relevant to the offspring of those affected and addicted individuals, for they may convey the same genetic risk (and susceptibility to addiction) to their children. Moreover, a possible association of dopamine system alleles with susceptibility to the pathogenic effects of stress and to disordered attention and anxiety regulation (Comings, Muhleman, & Gysin, 1996; Gill, Daly, Heron, Hawi, & Fitzgerald, 1997; Rowe et al., 1998) suggests that this profile of behaviors, seen more often among the offspring of cocaine-addicted individuals, may *for some* reflect a genetically based functional alteration or susceptibility in the dopamine system apart from or in addition to the effects of prenatal substance exposure. Though to date not studied in longitudinally maintained samples, it may also be that this same genetic vulnerability conveys a similar risk for addiction to these children as they reach adolescence. For example, adoption studies

show an increased risk of alcoholism and other drug abuse in adopted children whose biological parents were alcoholic whereas alcohol use by the adoptive parents did not increase the risk of alcoholism in the adoptive children if all other risk conditions did not prevail (Cadoret, Troughton, O'Gorman, & Heywood, 1986; Cloninger, Bohman, Sigvardsson, & von Knorring, 1985; Goodwin et al., 1974).

Thus, greater genetic susceptibility may be a strong predictor of risk for substance abuse compared to the impact of adoptive parents who use substances. At the same time, both genetic and environmental conditions may be important in the initiation of substance use; that is, environmental conditions and availability may contribute to an adolescent's initial experimentation with drugs, and progression to abuse and dependence may be mediated more by genetic factors. Studies of marijuana and cocaine use and the progression to dependence on either drug have been conducted in studies of monozygotic and dizygotic twins (Kendler & Prescott, 1998a, 1998b; Schukit, 1999) and have demonstrated that for both drugs, an adolescent's initial risk of using was related to both genetic and experiential factors, but the likelihood of an individual going on to abuse and dependence seemed more genetically conveyed.

Impact of Adolescent Substance Use

What are the consequences of adolescent drug use on other aspects of adult functioning? It is commonly assumed that adolescent drug use compromises most aspects of an individual's interpersonal, academic, and work life, but there are few longitudinal studies following an adolescent into young adulthood. Newcomb and Bentler (1988a, 1988b) followed 654 individuals who provided complete data at three testings over a period of 8 years, from early adolescence to young adulthood. Various types of teenage drug use, with the exception of alcohol use, but particularly cigarettes and hard drug use, had a range of negative consequences in young adulthood. These negative effects included problems with psychosomatic symptoms, dysphoric emotional functioning, impaired romantic attachments, and trouble with parents and family. Teenage drug use also increases job instability in young adults. Of particular importance, there is no single targeted area of impact of teenage drug use; rather, drug use impedes a range of important domains central to an adolescent's adaptive transition to mature adulthood. These observed effects are not the result of experimental or infrequent drug use, but of relatively heavy use during early and late adolescence. Heavy use, abuse, or misuse of substances in adolescence and not the occasional

social use at a party or among friends is associated with the overall serious impairments in later adult adjustment.

Marijuana has been particularly well studied for the impact on adolescents' educational performance and attainment (Lynskey & Hall, 2000). Increasing and sustained marijuana use is associated with poorer school performance, more negative attitudes toward school, and early school dropout (Ellickson, Collins, & Bell, 1999; Fergusson & Horwood, 1997; Fergusson, Horwood, & Swain-Campbell, 2002; Fergusson, Lynskey, & Horwood, 1996). Further, early cannabis use is associated with decreased college participation (Krohn, Lizotte, & Perez, 1997; Tanner, Davies, & O'Grady, 1999) and hence, fewer employment opportunities and less earning capacity. Additionally, long-term marijuana use produces subtle and selective impairments of cognitive functioning, which, although not usually severe deficits, nonetheless may impact an individual's job and educational adjustment (Solowij, 1999). Of particular importance, prospective studies (Lynskey, Coffey, Degenhardt, Carlin, & Patton, 2003) suggest that early, rather than later, use is associated with more problematic behaviors and complications, including continued substance abuse, risky sexual behavior, and criminal activity (Brook et al., 1998; Fergusson & Horwood, 1997). Although it is possible that a number of factors, including genetic factors (Plomin & Craig, 1997), may potentially contribute to these relationships (see later discussion), twin studies (Lynskey, Heath, et al., 2003) suggest that early use is associated for many youths with the adoption of an unconventional, more isolated lifestyle with easier access to drugs and for which early school dropout is one indicator.

PROTECTIVE FACTORS

Protective factors are conditions that can have their own independent effects on a given outcome and, at the same time, can moderate the relationship between risk factors and negative outcomes (Luthar & Zigler, 1991; Rutter, 1987). In the past decade, investigators have focused on the possibility that a number of protective factors may mitigate the impact of risk factors on the trajectory to substance use and abuse in adolescence (Hawkins et al., 1992; Wills, Vaccaro, & McNamara, 1992). Jessor and colleagues (Jessor, Van Den Bos, Vanderryn, Costa, & Turbin, 1995) studied students in grades 7 through 9 at four time points with repeated assessments of six measures of risk and seven measures of protection. The latter included attitudes toward school, health, behavioral deviance, and relationships with adults, as well as perceived level of control, selection

of friends as models of conventional or acceptable behavior, and participation in prosocial activities such as volunteering, school clubs, and activities with family. Across gender and ethnicity, students higher in protective factors (e.g., those endorsing more positive attitudes, greater perceived level of control, seeking friends as models of acceptable behavior, and engaged in more prosocial activities) had a much reduced risk of later problem behaviors, including substance use. Also, these protective factors moderated or reduced the relationship between those risk factors that were present to later substance use.

Level of self-control or regulatory abilities may be most central to the other aspects of protectiveness, including selection of friends and adaptive attitudes. Wills, Gibbons, Gerard, and Brody (2000) tested predictions from a self-regulation model of factors relevant for early onset of substance use with African American children. It was found that temperament characteristics were related to indices of behavioral self-control, and self-control indices were related to variables that either deterred or promoted substance use. In other words, protective processes reflected good self-control and involvement in school that in turn were mediated by temperamental characteristics such as good task attentional orientation and positive emotionality. Vulnerability processes were expressed through poor self-control and risk taking that also originated in temperamental dimensions of activity level and negative emotionality.

Coping abilities have been studied as protective or buffering factors against early substance use. A longitudinal study of children from seventh to ninth grade examined rates of alcohol, tobacco, and marijuana use and also styles of coping (Wills, Sandy, Yaeger, Cleary, & Shinar, 2001). Adaptive styles of coping were those that involved a child's active problem solving versus disengaged styles, including anger and avoidance. Those adolescents who typically used more active, problem-solving styles of coping were less likely to initiate substance use or to have peers that were involved with early substance use, whereas more disengaged styles were associated with higher rates of initiating substance use and of associating with substance-using peers. The impact of either style was greater when the adolescent had experienced significant life stressors; that is, more active styles buffered the relationship between life stressors and initiating substance use. It may be that those children with more active styles of problem solving are also more likely to gather information and consider alternative plans before acting, a form of self-control (Wills et al., 2001) that buffers the individual against the opportunities for experimenting with illicit drugs or using drugs as a means of coping during stressful times.

MODELS FOR A DEVELOPMENTAL TRAJECTORY TO SUBSTANCE USE AND SUBSTANCE DEPENDENCE

Returning to the distinctions among variables that serve as markers (fixed or variable), moderators, and mediators, the various risks and protective factors previously discussed may be placed in models for the initiation of substance use and for the trajectory from substance use to dependence. There is considerable work yet to be done to fully explicate these models.

The Model for Initiation of Substance Use

Considering first the initiation of substance use (Figure 16.1), it is likely, as discussed earlier, that genetic factors mediate an individual's initiation into substance use. One set of pathways by which genetic factors mediate the initiation of substance use involves the genetic basis for emotional regulation and self-control. These abilities influence individual development of emotional and behavioral capacities (e.g., on-task behavior, positive emotionality, and active problem solving) in early years that, in turn, mediate individual adaptation to the school environ-

ment (e.g., positive attitude toward school, good social skills) and, ultimately, successful school performance. Likewise, genetic influences on capacities for emotional regulation and self-control may be negative, mediating subsequent problems with emotional negativity and impulsive or risk-taking behavior. These less adaptive characteristics, in turn, may mediate the child's negative response to the school environment (e.g., a lower degree of commitment to school, disruptive behavior, conduct problems, poor social skills, and poor academic achievement) and, ultimately, failure at school.

As a child enters adolescence, his or her prior experience in the school setting may mediate peer choices at just the time when the peer group's influence on substance use initiation may be strongest. Children who have good emotional regulatory capacities and have experienced school success may be more likely to affiliate with prosocial peer groups that adhere to conventional societal norms and object to drug use. They may also be more likely to receive peer acceptance and support. Membership in a prosocial peer group may also further moderate the child's attitudes about school, drug use, social conventions, and social expectations. Likewise, if a child has had problems with emotional distress and impulsive behavior in early years and has not adapted well to the school environment, cumulative

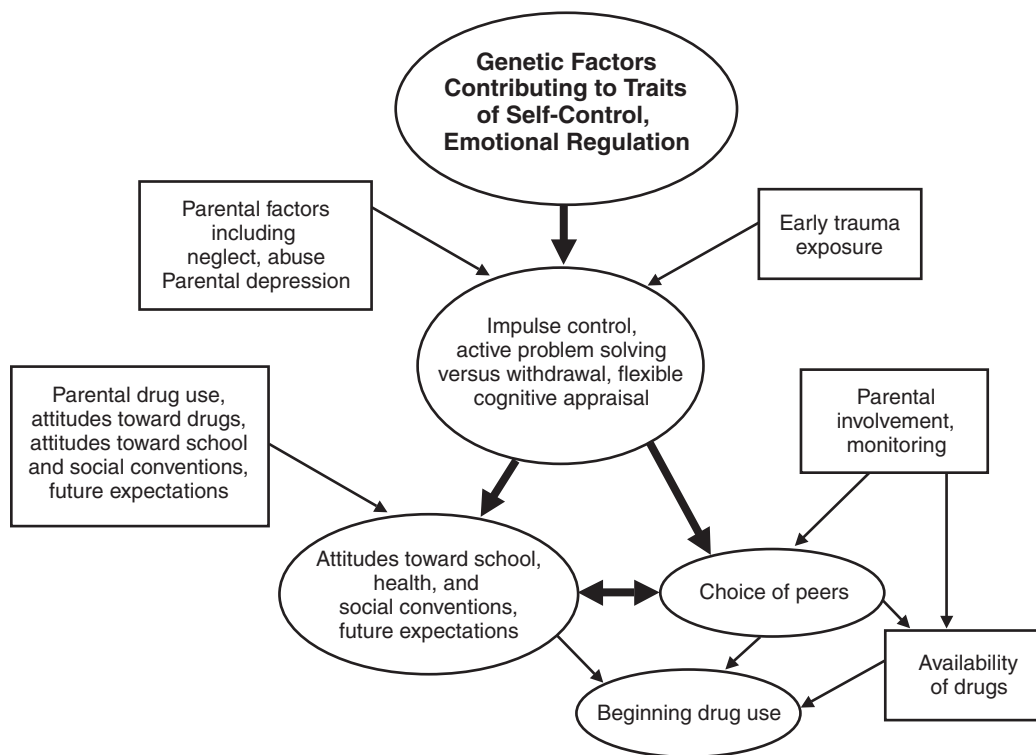

Figure 16.1 Model for initiation of substance use in adolescence.

risk may mediate his or her affiliation with a deviant or delinquent peer group that does not adhere to conventional societal norms, accepts drug use and early sexual involvement, engages in disruptive or delinquent behavior, and/or pressures its members to continue drug use. Membership in a deviant peer group may further moderate the child's attitudes about school, drug use, social conventions, and social expectations, further altering the trajectory toward initiation and experimentation. Alternatively, a child who has had any number of negative responses to school during early years may simply be rejected by adolescent peers, becoming socially isolated and alighting on a different but equally adverse trajectory toward initiating substance use.

The possible protective function of the child's capacity for emotional regulation and self-control (or the risk function of the inverse) must be considered in the context of family and cultural factors. First, genetic factors notwithstanding, some family factors, including early histories of abuse and neglect or exposure to trauma and violence, appear to directly alter individual emotional and stress regulatory capacities early in development, thus striking another pathway to substance use. Second, family acceptance of drug use (expressed in attitudes and/or drug use behavior) may lessen the perceived negative consequences of initial experimentation or use. Third, parental attitudes (e.g., academic aspirations and level of optimism about their children's future) and parenting behavior (e.g., levels of involvement and monitoring), particularly during early childhood, may alter the trajectory of the child's response to school during early years and the trajectory of peer involvement later during adolescence.

Societal acceptance of drug use, the legality versus illegality of a specific drug, or the presence of local neighborhood drug economies may also shift individual trajectories toward or away from initial experimentation and use at any time during childhood and adolescent years. For example, before the considerable health hazards of tobacco were well understood, smoking was an accepted, even positive mode of social interaction and friendship. In this kind of setting, initial use is more likely and also less negatively perceived, possibly even among adolescents whose individual trajectories otherwise confer more protection and less risk. The legal status of a drug removes the necessary involvement of criminal behavior as a deterrent to initiation or experimentation. The presence of an active drug-based economy in a local neighborhood setting not only conveys acceptance of substance use but also provides additional reinforcement for involvement in criminal activities that sustain the economy when buying and selling of drugs is

perceived as a faster means of gaining access to resources and social status.

The Model for Continued Substance Use and Dependence

The model for continued substance use and dependence also has a genetic component that mediates the trajectory for some, though not all, individuals (Figure 16.2). Indeed, problem use, abuse, and dependence may be more heritable and less influenced by environment than the initiation or use of substances, including alcohol and tobacco as well as illicit drugs (Kendler et al., 2000; Kendler & Prescott, 1998a, 1998b; McGue et al., 2000; True et al., 1997; Van Den Bres, Johnson, Neale, & Pickens, 1998). Other genes contributing to vulnerability for depression, anxiety, and/or Posttraumatic Stress Disorder may also play a role in an individual's move from early substance use to ongoing use and dependence.

Mood and disruptive behavior disorders appear to play a central moderating role in shifting individual trajectories from substance use to abuse and/or dependence. Multiple pathways, depending on the nature of disorder, appear to shift trajectories from use to abuse and dependence. For example, internalizing disorders, particularly depression and Posttraumatic Stress Disorder, may be an extension of emotional dysregulation that accelerates an individual from use to abuse and dependence. Alternatively, Conduct Disorder may be an extension of problems with behavioral control that also tip the scales toward dependence. However, the currently entangled etiologies of comorbid psychiatric disorders and substance dependence, as evidenced by their overlapping antecedents (e.g., family conflict and school failure) and patterns of mutual influence (e.g., drug use exacerbating mood, which, in turn, extends drug use), have so far made it difficult to discern empirically or clinically their mechanisms of interaction.

Individual gender specifically appears to moderate the ways psychiatric comorbidity moderates substance abuse and dependence. For example, for girls, depression is the most likely psychiatric moderator of substance abuse severity, whereas for boys, conduct disorders and attentional problems are more likely to influence this pathway.

Sociocultural factors (e.g., ethnicity) may also moderate the ways psychiatric comorbidity moderates substance abuse and dependence. In terms of ethnicity, being White appears to confer vulnerability for substance dependence when individual and interpersonal risk factors are present, whereas being African American appears to confer risk

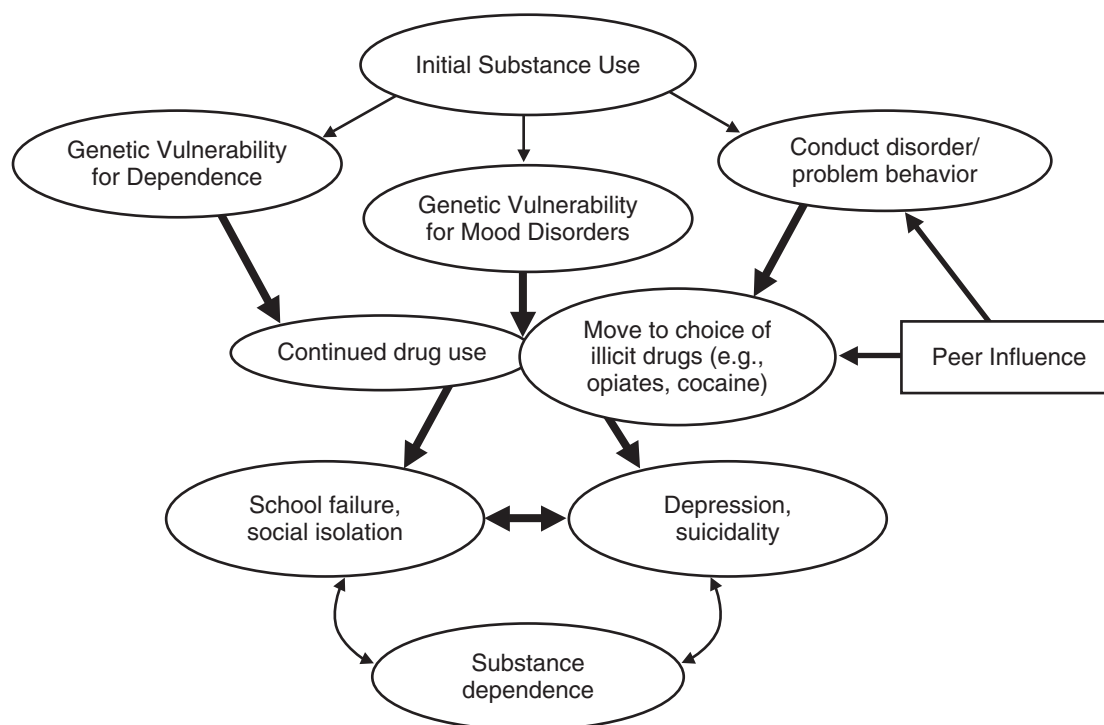

Figure 16.2 Model for progression to continued substance use and dependence.

when exposure to economic deprivation and academic failure are present.

Another prominent factor in determining pathways from substance use to abuse and dependence is the age of initial substance use. Initiation of use before 12 years of age increases the likelihood of dependence, suggesting that understanding the occurrence of risk in early years is going to be critical for understanding pathways to dependence.

The impact of ongoing substance use and abuse on social adjustment, peer relations, and work and school security also creates a cyclical effect by which substance abuse feeds continued dysphoria and a spiraling downward of an individual's environmental stability. For example, recent treatment approaches to substance dependence emphasize dramatic changes in an individual's social environment so as to diminish contacts with both stimuli that may accentuate drug craving and also provide opportunities for social contacts that are not connected with a drug-using world (Higgins, Heil, & Lussier, 2004; Thompson, 2003).

FUTURE DIRECTIONS

Considerable work has yet to be done to explicate fully the pathways to substance use and dependence proposed in

these models. Of particular importance, most of what is currently known about adolescent substance use and dependence is based on findings that have demonstrated correlation but not necessarily causation.

Mechanisms of Risk

The models presented here are best considered heuristic springboards rather than definitive maps. As Cicchetti and Cohen (1995) have suggested, distinguishing between factors that mark an event from those that play a causal role is a critical task to understanding how risk and protective factors work together to influence outcomes. Perhaps the greatest task now faced by developmental and addiction researchers is to move from identifying correlates to understanding their respective roles in causal risk mechanisms.

Future research will need to establish which among the currently known correlates operate in causal ways to generate substance use and abuse outcomes and how these risk mechanisms function and interact. Consider, for example, the respective functions of emotional regulation, coping style, and family dynamics in substance use. In the presence of adverse family dynamics, the capacity for emotional regulation may be a necessary causal factor promoting active problem solving, which, in turn, moderates the influence of

adverse family dynamics on an individual's substance use trajectory. In a more favorable family context, the capacity for emotional regulation and coping may be less critical. In other words, it may be that emotional regulation and coping style are important causal factors only when an individual faces environmental adversity or stress.

Equifinality and Multifinality

Model limitations notwithstanding, given the multitude of factors at varying levels of influence that have been identified as correlates in these early stages of investigation, the search for any one variable or pathway as *the* precursor to drug experimentation or abuse is not likely to be fruitful. Rather, the examination of patterns of developmental trajectories involving cumulative factors holds more promise for accurately mapping this complex phenomenon. Given the many potential trajectories to drug use initiation, the concepts of equifinality and multifinality (Cicchetti & Cohen, 1995) are particularly relevant to research and intervention development that aim to understand and alter adverse trajectories toward adolescent substance abuse and dependence.

Applying the concept of *equifinality* to the study of substance use initiation allows for the assumption that many divergent pathways can and will lead to the same outcome. For example, pathways to drug abuse and dependence for boys and girls appear to be carved through different risk mechanisms. For girls, internalizing disorders (e.g., depression) appear to shift trajectories toward prolonged use and dependence, whereas for boys, trajectories appear to shift in the presence of externalizing disorders. Similarly, pathways to substance abuse and dependence are influenced not only by membership in a socially deviant peer group but by social withdrawal and alienation from peers. Other examples of equifinality have yet to be examined. For example, in communities where teen idolization of drug- and crime-involved celebrities is considered socially deviant, pathways to drug abuse and dependence may occur only through membership in a disenfranchised peer group. In other communities, where teen idolization of drug- and crime-involved celebrities is considered more mainstream, pathways to drug abuse and dependence may more likely occur through membership in popular peer groups. Likewise, the increasing prevalence of substance abuse among adolescents in affluent communities suggests that alternative trajectories to substance abuse in the context of economic privilege also exist.

Applying the concept of *multifinality* to the study of initiation allows for the assumption that individual starting points that may confer risk (e.g., genetic disposition toward

poor self-regulation, parental acceptance of drug use) may or may not lead to drug use initiation, depending on the presence or absence of other intervening risk and protective factors. For example, as stated earlier, a temperamental predisposition to emotional dysregulation may confer risk only when specific constellations of environmental risk factors are present. In a context of frequent parental involvement and close monitoring, where optimism about the future and intolerance toward drug use are clearly expressed, a child with poor emotional regulation or self-control may remain on a trajectory toward relatively little experimentation. Alternatively, a child with good emotional regulation attending school in a neighborhood supported by a drug economy may easily become involved in peer networks where experimentation with substances is a social norm. In each case, the more commonly expected trajectory shifts based on the presence or absence of other specific risk mechanisms.

Implications for Intervention Research

Developmental interventions for children, adolescents, and parents can, at the same time, contribute to and benefit from the investigation of mechanisms by which substance use transitions to abuse and dependence. For instance, research that expands on developmental models of substance abuse by identifying key sources of influence over time (e.g., parents during early childhood and peers during adolescence) can help inform the timing and targeted population for specific intervention strategies. Longitudinal investigations in which individual trajectories of psychopathology and substance use are tracked over time may help determine which combinations of psychopharmacological and psychosocial interventions are likely to be most effective. Understanding the mechanisms by which problems in emotional regulatory capacities trigger substance use experimentation (e.g., the moderating role of the stressful environment) can help specify which populations of children at risk would benefit most from early childhood parenting interventions.

Carefully designed intervention research involving comparison groups, particularly in early phases when individual risk factors are targeted, can help clarify the mechanisms by which these targeted factors influence substance use. For example, the potentially causal role of self-regulation in substance use can be clarified by tracking substance use trajectories of children whose self-regulation improves in response to an early parenting intervention and comparing them with children whose parents were assigned to the control group. In other words, hypothesized causal mechanisms

of risk targeted in carefully designed intervention research (i.e., research in which integrity and intensity of intervention are monitored and a well-conceived control group is used in a randomized trial) can be tested by determining if improvement in the targeted risk factor favorably alters individual trajectories toward problematic substance use.

SUMMARY

Although prevalence estimates have been relatively stable in the past decade, a significant percentage of adolescents initiate licit and illicit drug use during their high school years. Genetic factors strongly contribute to the likelihood that an adolescent's early experimentation with drugs will progress to regular use and/or dependence, but in addition, peer group, availability of drugs, and community acceptance are important contributions. Adolescents who begin their drug use early are at much greater risk for continued use and dependence as well as for the associated comorbidities of school dropout, social isolation, and involvement in criminal activity. Protective factors include perception of a high level of self-control and of stable, caring peers and adults. Models describing the trajectory from early to regular use and dependence are necessarily multivariate and causally interactive, with no one factor being singularly predictive for the likelihood or severity of later dependence. Research that (1) examines multiple pathways to substance use and dependence, (2) identifies protective factors that can alter adverse trajectories, and (3) tests hypothetical causal mechanisms of risk is likely to be the most fruitful. Investigations involving intervention development can be particularly useful in the confirmation of causal mechanisms.

ALCOHOLISM AND THE ALCOHOL USE DISORDERS

In 1980, with the advent of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-III)* (American Psychiatric Association, 1980), Alcohol Use Disorder (AUD) replaced the broader umbrella of alcoholism by distinguishing between recurring alcohol use concomitant with problems but lacking tolerance, dependence, and compulsive alcohol-seeking behavior (alcohol abuse) and recurring use with those three characteristics present (dependence). *DSM-IV* (American Psychiatric As-

sociation, 1994) continues that differentiation. I use the term AUD when I refer to the umbrella of both, and the differentiated terminology when issues relating to distinguishing features need to be addressed.

Preparation of this chapter was supported by grants from the National Institute on Alcohol Abuse and Alcoholism (R37 AA07065, R01 AA12217) and the National Institute on Drug Abuse (R01 DA15398 and U10 DA13710). I am also indebted to Stephanie Herzberg, Ru Knoedler, and Lisa McLaughlin for their considerable help in putting this chapter together.

HISTORICAL INTRODUCTION AND ISSUES FOR THE FIELD

Evidence that alcoholism runs in families has been present in the literature for at least 200 years (Hogarth, 1751; Rush, 1790), but the definitive evidence that this assortment had a genetic basis has only gradually accumulated in the past 30 years (Cotton, 1979; R. L. Hall, Hesselbrock, & Stabenau, 1983a, 1983b; McGue, 1994). The landmark study of the modern era that firmly established a heritable basis for the disorder was the adoption study of Donald Goodwin and colleagues (Goodwin, Schulsinger, Knop, Mednick, & Guze, 1973), conducted in Denmark and involving children born to alcoholic and nonalcoholic parents who were adopted away in early life. Although subjected to strong challenges from staunch environmentalists (Searles, 1988), the Goodwin study and others to follow have repeatedly demonstrated that the disorder has a substantial heritable component (McGue, 1994; McGue, Pickens, & Svikis, 1992; Prescott et al., 2005).

Studies in the early 1980s, most notably that of Cloninger, Bohman, and Sigvardsson (1981) but supported by work from several other groups (Babor et al., 1992; Hesselbrock et al., 1984; Zucker, 1987), were critical in taking the discourse to another level by providing strong evidence for heterogeneity of the phenotype, with different patterns of heritability, psychiatric comorbidity, course, and severity found among them. Although this author in 1987 summarized evidence for at least four subtypes, the preponderance of work in the field until quite recently has focused on only two (Babor, 1996; Windle, & Scheidt, 2004). Type I, also called *milieu limited* by Cloninger (1987), was observed in both men and women and involved adult onset, relatively moderate symptomatology, a low or absent psychiatric comorbidity, and a shorter course. Heritability was mild, and the evidence suggested that development of the alcoholic phenotype was heavily influenced by risk factors in the social environment. Type II or *male-limited* alcoholism was marked by early onset (late adolescence through early adulthood), strong heritability (typically marked by a dense family history, positive pedigree, and passed through the father), severe symptomatology, and aggressive/antisocial comorbidity. Later work (Kendler, Heath, Neale, Kessler, & Eaves, 1992; McGue, Pickens, & Svikis, 1992; Pickens et al., 1991) challenged the male-limited nature of this subtype and demonstrated significant, albeit lower heritability among women, but continued to show lower transmission of drinking problems and conduct problems.

Although this more recent work conceptually paid tribute to the importance of environmental factors in shaping the eventual diagnostic outcome, the dominant perspective was that “alcoholism is a genetic disorder” (National Institute on Alcohol Abuse and Alcoholism, 1985), and the conceptualization of the epigenesis of the disorder was a heavily bottom-up model. In fact, one prominent genetic researcher of that era made the assertion as recently as 5 years ago that environmental factors would only be important *after* the “alcoholism” genes were discovered, at which time the manner in which the social environment moderated their expression would be of scientific and preventive interest. Social and psychological influences were viewed as risk factors for drinking behavior and drinking problems in adolescence, but their potential impact on developmentally later clinical-level phenomena was discounted (cf. Fillmore et al., 1991; Zucker & Gombert, 1986).

In contrast, the dominant scientific paradigm for understanding the emergence and maintenance of drinking behavior (not alcoholism) has been sociological and social psychological. Some 40 years ago, the sociologists George Maddox and Bevode McCall (1964) made the point that the use of alcohol is a social act within a larger society whose dominant perspective is that alcohol use is “good.” In that broader context, alcohol use is perceived by teenagers as one of the markers of entry into adult status, along with the initiation of sexual activity and obtaining the right to drive an automobile (Maddox & McCall, 1964). Explanations of the emergence of drinking behavior have sustained this social psychological emphasis ever since and have targeted peer influences as major instigators of the initiation of drinking on the one hand, and the transition into problem drinking on the other. Peers serve as role models as well as proximal sources of availability in a society where purchase before age 21 (until 1988, age 18) is illegal. Such explanations are suitable to handle the normative behavior of the general population, where median age of first use is 14 and where median age of first drunkenness is 17 (Johnston, O’Malley, & Bachman, 2003).

However, a normative explanation is not sufficient to handle the substantial individual differences known to occur in adolescence, and it likewise can only poorly handle the fact that not all adolescents move from drinking to drunkenness or to other problem use and that others start substantially earlier than adolescence. Approximately 20% of the population are still nondrinkers in 12th grade (Johnston, O’Malley, & Bachman, 2001), whereas 9% have started drinking by 11 to 12 years of age and 5% have started by ages 9 to 10 (Johnston, O’Malley, Bachman, &

Schulenberg, 2004a). To account for this variability, in the late 1960s and 1970s, Richard and Shirley Jessor (and later with the collaboration of John Donovan) developed a social-psychological conceptual framework called “problem behavior theory” (Jessor & Jessor, 1977) that incorporated this normative explanation for drinking behavior into a general model of adolescent development. In problem behavior theory, the acquisition of alcohol and other drug taking behavior, as well as its progression into problem use, is viewed as part of a broader developmental process that encompasses (1) the *social context* of neighborhood, church and other formal religious groups, social class, and family; (2) the *personality system*, including values and expectancies about alcohol and other drugs, but also about the broader social environment; and (3) the *behavior system*. Within the personality system are included values and expectancies about independence versus achievement, about feeling integrated versus alienated from others, about one’s sense of internal versus external control, and about the extent of acceptance and tolerance of deviant behavior.

An extensive series of studies by these investigators and others since have shown that the transition to involvement in the problem behaviors of adolescence was predictable by this theoretical model. These studies also demonstrated that each of these “problem behavior” variables, including the earlier use of alcohol, the use of marijuana and other illicit drugs, involvement in problem alcohol use, and earlier sexual experience, had substantial variance in common and could all be subsumed within a “general deviance” factor (Donovan, Jessor, & Costa, 1988; McGee & Newcomb, 1992; Sadava, 1985). The advantages of the theory are that it connected a number of behaviors previously regarded as unconnected, it predicted who would transition into use as well as progress to more problematic alcohol or other drug involvement, and it tied these behavioral adaptations into a much broader matrix of both personality structure and the social environment. The strength of the theory was also demonstrated by its ability to predict decline in these activities as development proceeded from adolescence into early adulthood (Jessor, Donovan, & Costa, 1991).

Although not heavily emphasized by the Jessors, problem behavior theory is of special interest because it focuses on a core transition from socialization by parents, including acceptance of their values and guidance, to reliance on peers as a source of both norms and social reinforcement. Insofar as the adolescent peer culture emphasizes independence from parents and experimentation with deviant behavior, this becomes the normative choice of that age stage. With the move into adult status, a different set of values involving greater conformity come to the fore, and

problem drinking behavior decreases (Bachman et al., 2002). This has been a highly useful and powerful theory that integrates individual behavior with influences from the proximal social environment. The theory also implicitly specifies that behavior is developmentally responsive to the changes in role demands imposed by the larger society that occur with the transitions from childhood to adolescence and from adolescence to adulthood. To that degree, it was a harbinger of life course theory, articulated by Glen Elder (1998) a generation later.

These two literatures, one on the etiology of adult AUD and the other on the development of drinking and adolescent problem drinking, remained largely independent of each other until the late 1980s and early 1990s, when a number of studies were initiated on high risk for alcoholism and other drug use beginning in childhood and early adolescence (Brook, Whiteman, Cohen, & Tanaka, 1992; Chassin, Barrera, Bech, & Kossak-Fuller, 1993; Cohen, Cohen, & Brook, 1993; Tarter et al., 1999, 2003; Zucker, 1987). These studies incorporated a developmental psychopathological framework (Cicchetti & Cohen, 1995) and utilized epigenetic models to varying degrees. Even with this progress, and with explicit, theory-driven reviews on the issue periodically appearing (Tarter et al., 1999; Zucker, Boyd, & Howard, 1994; Zucker, Fitzgerald, & Moses, 1995), the field is still far from embracing this framework. Although it is gratifying to see that the lead institute for alcohol research, the National Institute on Alcohol Abuse and Alcoholism (NIAAA), now accepts that alcoholism is both a genetic and a developmental disorder (Li, 2004), the progression into AUD is described as taking place between adolescence and adulthood, and the manifest evidence that the process begins much earlier is still not appreciated. I return to this issue later in the chapter.

The multilevel causal structure coming out of these different disciplinary frameworks is a large one to integrate, and most scientists and working groups lack the multidisciplinary training and collaborative network to allow this to happen. Thus, the development of the field has to a degree remained split between the biomedical and the psychosocial, as evident even in the Program Committee structure of the Research Society on Alcoholism, the primary international scientific society focusing on these problems. Despite the large nature of the integrative task, in our chapter in the first edition of these volumes (Zucker, Fitzgerald, et al., 1995) we advanced a developmental systems perspective (Ford & Lerner, 1992) on the etiology of AUD. We also made that case that this was the only framework sufficient to effectively handle the multilayered etiology of these disorders. The present chapter continues to utilize

this formulation. The reader will judge whether this effort has been successful.

In the remainder of the chapter, we review the epidemiology of both Alcohol Use Disorder and earlier alcohol involvement. We then articulate the developmental systems framework that guides the content of this review. We follow this scaffolding in laying out the risk structure, course, and heterogeneity of the disorder. The chapter concludes with a section on future directions for the field.

EPIDEMIOLOGY

Table 17.1 provides the 12-month and lifetime prevalence rates (in percentages) for *DSM-III-R* alcohol abuse and dependence, based on the National Comorbidity Study (NCS) of U.S. population estimates for the noninstitutionalized civilian population between the ages of 15 and 54 years (Kessler et al., 1994). To give a larger perspective on the problem, rates for other drug abuse and dependence are also presented.

A number of points about these rate variations are of importance:

1. Alcohol abuse and dependence are the most common of the substance use disorders.
2. Among men, 1 in 3 adults have at some point in their lives met either abuse or dependence criteria.
3. Gender differences are significant and are of the order of 2:1 for abuse and 3:1 for dependence.
4. Abuse without dependence represents 40% of the life course problem and 26% of the current (12-month prevalence) problem. Or, to put these figures in a slightly different perspective, 40% of the lifetime national problem is of subclinical proportions but involves socially and personally significant misbehavior (e.g., compromised driving, risky sex, date rape, job absenteeism, neglect of household responsibilities). These data also indicate that the diagnostic burden of abuse in any year will be a smaller proportion of the AUD burden than it will be for the nation over time. This is so because the abuse diagnosis is less likely to recur than the dependence diagnosis, but it will ultimately involve more people.
5. In addition, because of gender differences in abuse versus dependence, abuse is a relatively greater problem among women, accounting for 30% of the 12-month total problem, but accounting for only 24% among men.
6. Other drug disorders are substantially less of an issue than alcohol abuse/dependence, with a ratio of 12-month alcohol to drug disorder of 2.7.
7. Other drug disorders are to a large degree superimposed on alcohol use disorders, given that only 14% of 12-month drug disorders occur without a concomitant alcohol diagnosis.
8. The visibility of other drug disorders is likely because the disorders are more dramatic, hence socially compelling, because they appear to be more of a threat to the social order (e.g., because of their links with crime, as well as out of the belief that they may be less responsive to treatment) and because the social costs involved in interdiction and treatment are proportionately much larger. The lay view, as well, is that the disorders occur in isolation, which heightens the differentiation between the types of drug involvement.

Related to these points but not shown in the table, AUD is the nation's most prevalent disorder, with 23.5% of the adult population reporting symptomatology that qualifies for an abuse or dependence diagnosis at some point in their

TABLE 17.1 Lifetime and 12-Month Prevalence of UM-CIDI/*DSM-III-R* Substance Use Disorders (Percentages)

Disorder	Total		Male		Female	
	Lifetime	12 Months	Lifetime	12 Months	Lifetime	12 Months
Alcohol abuse without dependence	9.4	2.5	12.5	3.4	6.4	1.6
Alcohol dependence	14.1	7.2	20.1	10.7	8.2	3.7
Alcohol abuse/dependence combined	23.5	9.7	32.5	14.1	14.6	5.3
Other drug abuse without dependence	4.4	0.8	5.4	1.3	3.5	0.3
Other drug dependence	7.5	2.8	9.2	3.8	5.9	1.9
Other drug abuse/dependence combined	11.9	3.6	14.6	5.1	9.4	2.1
Any substance abuse/dependence	26.6	11.3	35.4	16.1	17.9	6.6

lives (Kessler et al., 1994). Thus, the set of problems encompassed by this disorder is an extraordinarily large one.¹

A major point of this chapter is that the adult disorder does not emerge full blown in adulthood, but rather develops over time in a process for which childhood precursors are identifiable. To home in on the early harbingers of this process, Table 17.2 presents national data on first alcohol use and drunkenness onset, the latter selected as an indicator of early problem use. Data are 10th-grader retrospective reports from the Monitoring the Future (MTF) study (Johnston, O'Malley, Bachman, & Schulenberg, 2004b). The 10th-graders' data are utilized rather than those from another age group because, as Johnston et al. note, younger informants are likely to more literally interpret questions about first use and overreport on "first drink" experience. Conversely, to use 12th-grade informants is to lengthen the time interval for retrospection and also to increasingly lose heavier-using respondents because of their greater likelihood for school dropout. These data indicate that alcohol use has already begun for 1 out of 20 10-year-olds; by age 15, 60% of the population have had some drinking experience. The drunkenness data, taken as an indicator of incipient problem alcohol involvement, show that 1% of 10-year-olds have already crossed this threshold, and by age 15, the rate is about 33% of the population. Moreover, when these figures are broken down by gender, more than 50% of all boys meet this criterion at age 15.

Other MTF data make the case for early problem involvement even more compellingly. Thus, 11.9% of eighth-graders (ca. age 14) report they have had five or more

drinks in a row at least once in the past 2 weeks (Johnston et al., 2004b, p. 504), and a fifth of that group (2.3% of the population) report this consumption level 3 to 5 times or more during the 2-week interval² (Johnston et al., 2004b, p. 102). To recast these figures, given that drinking for adolescents is heavily confined to weekends, this high-end group of approximately 1 out of 8 14-year-olds is reporting drinking at adult heavy-drinking levels, and a fifth of that group, involving 5% of drinking 14-year-olds, is indicating that they are drinking at adult heavy-drinking rates at most available opportunities. Using *DSM-IV* criteria, and assuming any additional trouble related to the drinking (a not unreasonable assumption at this age), behavior sufficient to achieve a diagnosis of alcohol abuse has already been achieved by that group.

At the same time, it would be a mistake to presume that everyone with early signs of problem use will go on to develop an Alcohol Use Disorder. As already noted, the adolescent developmental literature has been clear that early alcohol use as well as alcohol problems need to be regarded as one component of a deviance syndrome. The syndrome emerges in adolescence and is adolescence-specific in the sense that the majority of individuals with such problems do not go on to develop adult disorder, al-

¹ Although these rates vary somewhat from survey to survey and when using different measurement criteria to establish a diagnosis (e.g., Grant, 1997; Narrow, Rae, Robins, & Regier, 2002), the basic story remains unchanged.

² The 5 drinks/occasion measure, sometimes called binge drinking, was originally used in MTF and other surveys as an index of heavy and potentially problematic drinking, hence the use of the term "binge" even though this consumption level is substantially less than what would occur in an alcoholic binge. A more recent referent for the measure, developed by NIAAA, suggests the measure is still a useful problem indicator. As pointed out by NIAAA (2004): If a typical 160-pound male drinks 5 standard drinks over a 2-hour period, he would reach a BAC of .08, making him legally intoxicated in all 50 states.

though some may reach diagnosable levels during their adolescent years (Blane, 1979; Donovan & Jessor, 1985; Jessor & Jessor, 1977). Conversely, the problem prevalence figures, especially for those still in grade school, suggest that some etiologic factors have already been in place by the time middle school is started. Despite the ready availability of these incidence data, which drive the point home, this is not yet a widely known fact. Here and there one can find accounts in the clinical literature of the previous generation (e.g., Mitchell, Hong, & Corman, 1979) and even as far back as a century ago (e.g., Madden, 1884), which call attention to these occurrences of very early and very severe child alcohol involvement. The effort to account for such beginnings leads us to cast an etiologic net considerably earlier than adolescence. I do so later in the chapter, when dealing with the evidence about variations in risk and course of the disorder. However, this issue of differences in course, and a related set of questions about how many different variations there may be, what their determinants are, how best to describe and understand them, has become a major set of questions for the field because it encompasses issues of phenotypic heterogeneity as well as definitional issues about what the “true” nature of alcoholic disorder might be. I also return to that set of questions later.

A MULTILEVEL NET FOR DEVELOPMENTAL VARIATION

Although it may seem a trivial point that one cannot have alcohol problems without the presence of alcohol, it is not trivial that such presence is regulated by societal norms about appropriate contexts of use and the availability of the drug in society. At the same time, alcohol is not just a social object; it is also a drug, and understanding the pharmacodynamic and neurodynamic matrix of its action on the human organism is essential to understanding how the symptomatology of AUD comes to be. To chart the manner in which these causal structures interact requires model building that will cross multiple levels of analysis and multiple disciplines, operating over social, individual, and biological time (Cacioppo, Berntson, Sheridan, & McClintock, 2000; Cicchetti & Dawson, 2002). This perspective is inherent to a developmental psychopathological framework, but it is not one regularly embraced by substance abuse researchers. To capture such a multilevel structure, a developmental systems framework (cf. Ford & Lerner, 1992; Sameroff, 1995) is essential as a means to organize these diverse levels of action.

This is simultaneously both a challenging and an intriguing interdisciplinary puzzle that sets the psychopathology of addictive disorders apart from their sister disorders. Although such macro- and microlevel influences may play *some* role in the anxiety disorders or Schizophrenia or depression, the macrostructure can to a much greater degree be ignored for the nonaddictive disorders, at least in the early levels of analysis. It cannot be for the substance use disorders, and for Alcohol Use Disorder in particular, given the central role that alcohol plays in civilized society (Pittman & White, 1991). The magnitude of the disorder’s prevalence is also a testimony to the magnitude of the drug’s social presence, as indexed by its availability and use.

AUD rates have been shown to vary with larger economic trends that impact the rate of employment and unemployment (Brenner, 1973) and the level of production of alcohol in the society (Edwards et al., 1994). Even population density, as it indexes living in an urban versus a rural environment, has become a useful explanatory mechanism for some of the variation in individual consumption patterns and ensuing problems (Edwards et al., 1994; Fitzgerald & Zucker, 1995). At the most distal level, the social regulatory structure influences manufacture and distribution of this beverage/drug, sets the rules that tax its sale, makes the drug legal or illegal to use at different ages, and also determines whether distribution can legally take place in the community. It is this social control structure that also sets the penalties for illegal or inappropriate use, which function as both threat and deterrent to those contemplating the illegal act. The evidence is clear that such controls affect individual behavior. Thus, a shift in the legal drinking age from 18 to 21 decreased drinking and driving accidents significantly during the age 18 to 21 period (Wagenaar & Toomey, 2002). A spread of effect beyond the age period within which the law had applicability has also been observed. Lower drinking rates were found in the subsequent 21- to 25-year age period as well (O’Malley & Wagenaar, 1991).

Etiologic models that currently dominate the field have either largely ignored this macrostructure or dealt with its effects at the neighborhood and local social environmental level. In only a few instances has work been done that examines interface phenomena such as the manner in which larger social forces influence individual alcohol-seeking behavior (Edwards et al., 1994). To provide but one example, the “wetness or dryness” of the society (Skog, 1985) changes the threshold within which microlevel phenomena such as alcoholism diagnostic subtypes will appear (Helzer & Canino, 1992; Reich, Cloninger, Van Eeerdewegh, Rice,

& Mullaney, 1988); a wetter society will increase the rate of AUD in its population, a drier one decrease it. Another longer-term effect of such influences is that a lower level of genetic susceptibility is more likely to be expressed in higher- as compared to lower-consumption societies because drinking rates will be higher in the higher-consumption environment. Under those circumstances, even persons with a higher genetic threshold of susceptibility will be more likely to move into diagnosis because they are more likely to drink heavily due to greater environmental cuing (for other examples of such interactions, see Kuh, Power, Blane, & Barley, 1997; Rose, Kaprio, Winter, Koskenvuo, & Viken, 1999).

Variable networks more proximal to the individual have also been shown to significantly predict level of alcohol involvement. These include variations in socialization practices, which create differential inculcation of values about the desirability of alcohol use. These values in turn foster the development of expectancies stimulating or dampening earlier use and stimulating or dampening expectancies about the effects the drug will have. A considerable amount of evidence exists that such learning plays a causal role in eventual alcohol involvement (Gaines, Brooks, Maisto, Dietrich, & Shagena, 1998; Goldman, Del Boca, & Darkes, 1999; Smith, Goldman, Greenbaum, & Christiansen, 1995), and some newer work indicates that it also plays a role thereafter in whether or not there is progression into problem use (i.e., drunkenness and binge drinking; Jester et al., 2005).

This multitiered influencing structure of sociocultural and relational systems is bounded at its lowest level by individual behavior that is only partially regulated by social influences. That boundary is also an upper-level limit on a second multidomain influencing structure, located within the individual, that plays a major role in determining life course variations in alcohol use and alcohol dependence. Patterns of use are known to be regulated by cognitive and motivational networks, determined by the user's subjective experience of the drug, the user's knowledge of the rule structure for appropriate use, and a subjective probability computation of whether it is more or less desirable to go about drinking at a given point in time (Dunn & Goldman, 1996). The immediate encouragement and availability offered by peers regulates onset and course not only through social reinforcement, but also through cuing. The timing of when initial use takes place and the development and maintenance of problem use are heavily influenced by the patterns of alcohol use occurring in the surrounding peer structure. The concomitant presence of individual behavioral repertoires that encourage such use (e.g., risk taking, antisocial

behavior) also heighten the likelihood that drinking problems will emerge and be sustained (Hawkins et al., 1997).

At the same time, alcohol-related disorders are brain disorders, involving the brain's structures for appetite, reward, planning and forethought, and affective and behavioral control. It is also essential to recognize that alcoholism is a complex genetic disorder, with a heterogeneous phenotype. It fits the genetic definition of a complex trait: It shows familial aggregation, its transmission patterns do not follow Mendel's laws, and it appears to result from more than one genetic locus and more than one aspect of the environment (Risch, 1990; Sing, Haviland, & Reilly, 1996).

The within- and across-domain interactive system presented so far has primarily been described in the vertical language of top-down and bottom-up relationships, to the neglect of the other major dimension of the system: time. As noted at the beginning of this section, multiple times influence these relationships. They range from cultural time (involving stability or change in patterns of alcohol availability, use, and diagnostic prevalence among different cohorts), to social time (involving variations in the character of relationships at different age stages, as a function of the social timetable and rule and role structure of the society), to individual time (involving developmental and maturational changes), to biological time (involving the turning on, turning off, tuning, development, and degradation of biological systems over the course of aging). These relationships are captured by the terse observation that alcoholism is a developmental disorder. They also are captured by the observation that substance abuse is a chronic, remitting disorder (McLellan, Lewis, O'Brien & Kleber, 2000). Both observations underscore the dynamic nature of top-down and bottom-up relationships as development proceeds. They also imply that the nature of the interactive relationships may not be constant across the life span, as social and biological climates shift with changing historical, social, and developmental time parameters. Figures 17.1 and 17.2 illustrate the nature of these relationships more concretely.

Figure 17.1 is my elaboration on Elder and Caspi's (1990) three-dimensional life course grid. It shows the multigenerational linkage of individual, family, and historical events across three generations. The x axis depicts cohort time for the twentieth century, showing major marker events throughout the interval that have shaped the course of the societies taking part in them. An individual born around 1915 has had a different experience of alcohol and other drug availability during an adolescence marked by Prohibition than did one born in the early 1950s, who experienced adolescence during the Vietnam era's advocacy of "turning on, tuning in, and dropping

Generational Cohort

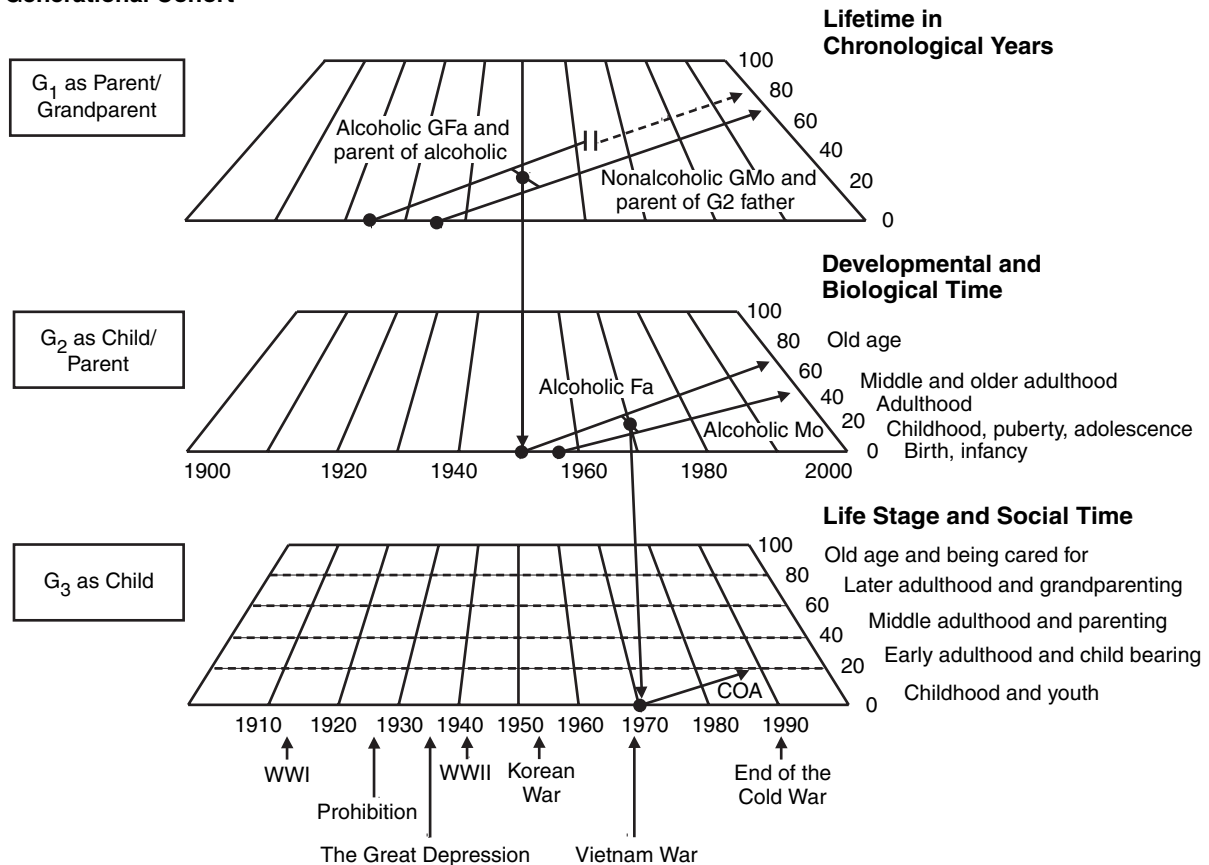

Figure 17.1 The multigenerational linkage of life course trajectories in individual/developmental time, life stage time, family time, and historical time.

out” (Holdcraft & Iacono, 2004). The y axis is simultaneously one of life stage/social time, developmental/maturational time, and biological time. Although these dimensions are obviously correlated with each other, the relationship is far from perfect. The example in the figure depicts a grandparental generation (G₁ cohort) with an alcoholic grandfather born just before the advent of Prohibition, whose life ends in suicide at age 40. He is married to a nonalcoholic spouse who was born toward the end of the Great Depression. The two have a son born just after the end of World War II. The grandmother continues to live into her 70s. Her son (G₂ cohort), who also becomes alcoholic, experiences his father’s death at around age 10. He marries a woman who is also alcoholic, and the two bear a son (G₃ cohort) in 1969, during the Vietnam era. The son has a low-normal IQ and is impulsive, and there are soft signs of the presence of fetal alcohol effects. This diagram illustrates how both historical and family events can have different impacts on trajectories of the next (or even the subsequent) generation, as their unique chronol-

ogy impacts a different life stage for the younger generation’s members (Elder, 1998). The figure also shows how each parent’s influencing structure projects downward onto the child’s developmental trajectory, with influence both at the point of conception by way of genetic endowment, as well as developmentally thereafter.

Figure 17.2 provides a more detailed schematic of the nature of the bottom-up and top-down structure at the variable level. This heuristic diagram is derived from Charles Sing’s (Sing et al., 1996) model of the genetic architecture of complex diseases, but the variable network has been modified to make it suitable for Alcohol Use Disorder; the diagram also depicts the contribution of top-down environmental variation in the process, an element not characterized in Sing’s account. The figure shows the reaction surface of individual alcohol problem variation (or its proxy, alcohol problem risk, at ages where use does not yet occur) across the age span. This surface of individual symptomatology (number of problems) is shaped by both the top-down structure (abbreviated here from the

Figure 17.2 Probability of drug abuse (risk) over the life course: the envelope of risk expression as a function of genes, intermediate traits, environment, and life stage.

multigenerational structure depicted in Figure 17.1) into a single index of degree of risk enhancement versus risk dampening provided by the environment and by the bottom-up variable network.

In a chronologic sense, the causal structure of the end point phenotype begins with the polygenetic network at the gene level. This is a set of variables that remains unaltered from conception onward. Genes interact in combinations to produce a network of intermediate traits (alternatively termed “endophenotypes”; Gottesman & Gould, 2003), and these interactions in turn are influenced by the risk-dampening/risk-enhancement network, a network that is not constant as development proceeds. The unevenness of the reaction envelope of alcohol problem expression across levels of environmental risk, even at the same life stage, indicates that the impact of genetic risk may vary as a function of the environmental risk-dampening/risk-enhancement structure.

VARIATIONS IN RISK AND COURSE OF THE DISORDER

When does risk for alcohol involvement begin? It is extremely rare to see a 5-year-old consuming alcoholic

beverages; as already noted, the normative expectation among youth, as well as the modal behavior in American society, is for self-initiated drinking of alcoholic beverages to commence around age 14. The problem use figures also slowly move upward with age, with 22% of 10th graders, 28% of 12th graders, and 40% of 21- to 22-year-olds reporting binge use in the prior 2-week period (Johnston et al., 2004b, 2004c). At the same time, age progression is, of itself, not an explanation of process but rather a chronological marker of other events that lead to onset or problem use. Thus, individual differences in age of onset are attributable to differences in the rapidity of emergence of the underlying causal event structure. The developmental question then becomes one of specifying the events and circumstances in which they show up.

From this perspective, neither first drinking experience nor first bingeing experience is the beginning of the process of alcohol involvement, or even of the emergence of alcohol problems, abuse, and dependence. Alcohol has a place in the ritual practices of many religions and thus allows children to have some minor consumption experience well before they have made any conscious decision to drink (Glassner, 1991; D. B. Heath, 1991). Moreover, media exposure assures that some knowledge of alcoholic beverages is present even before peers offer the opportunity for drinking to take place (Atkin, 1995; Wylie, Casswell, & Stewart, 1989). More generally, for regular (volitional) drinking to take place, first, the potential user implicitly needs to be aware that there is a class of substances collectively known as alcoholic beverages; second, he or she must know that these substances have certain properties (effects) connected to their ingestion; and third, such effects need to be viewed as sufficiently desirable to mobilize the individual to engage in alcohol seeking (or at least alcohol accepting). These properties, collectively known as implicit cognitions (Stacy, 1997; Stacy, Ames, Sussman, & Dent, 1996) and outcome expectancies (e.g., Goldman, Brown, Christiansen, & Smith, 1991; Rather, Goldman, Roehrich, & Brannick, 1992), have been shown to predict subsequent adolescent drug use, as well as to be direct effect predictors of both alcohol and other drug use (Smith et al., 1995; Stacy et al., 1996). The theoretical base for this work has been the social cognition and memory process literatures (e.g., Ajzen & Fishbein, 1980; Tiffany, 1990), which have emphasized not only the representational but also the motivational attributes of internally constructed cognitive models (schemas). From the perspective of the observer, the actual “decision making” may appear too rapid for this to occur. But a now volumi-

nous literature involving carefully controlled laboratory studies has shown how the underlying details that shape the decision making can be identified. A complex interplay of affective as well as rational elements is factored into the subjective equations that underlie ongoing drinking behavior, as well as the decision making about whether one should initiate drinking in specific situations or refrain (Fischhoff & Quadrel, 1995). The developmental question is, How and under what conditions are these elements learned?

Within this conceptual tradition, a series of developmentally earlier studies using methods that allow children to tell the experimenter about their knowledge of the rules that govern alcohol use have shown that preschoolers in the general population already know two of the core alcohol use schemas of the larger culture: The children, even at ages 3 to 5, already attribute alcoholic beverage consumption more to adults than to children and more to adult males than adult females (Noll, Zucker, & Greenberg, 1990). In addition, the ability to identify alcoholic beverages by smell (an indicator of personal exposure rather than simply media exposure) was both age-graded and based on experiences in the home. Older children were better at identifying these beverages than younger ones, and the ability to recognize alcoholic beverages was directly related to the amount of alcohol the parents consumed, as well as the degree to which their parents' reported use of alcohol for "escape" reasons.

A logical extension of this work is the examination of possible differences in schema structure in high-risk populations such as children of alcoholics (COAs), for it is here that exposure differences would be most likely expected and also where the early identification of "risky cognitions" would be anticipated to be of greatest long-term significance. Zucker, Kincaid, Fitzgerald, and Bingham (1995) explored this possibility by examining differences in alcohol use schemas in preschooler COAs and suitably age-matched children from nonalcoholic homes. They asked children to identify photographs of alcoholic beverages and examined the degree to which alcoholic beverage use was attributed to people depicted in common situations where beverages are consumed (e.g., at a meal, on a picnic, at an adult party). COAs were more likely to identify at least one alcoholic beverage and were better able to correctly identify specific alcoholic beverages. Differences in the children's attributions of alcoholic beverage use to adults were again predicted by their parents' reported level of alcohol consumption. In short, alcohol schemas relating to both knowledge and use were more common in the alcoholic families.

Empirical work has yet to demonstrate the manner in which such schemas relate to the emergence of actual drinking-onset behavior in later childhood, but other research on the cognitive organization of such schemas as observed in second- to fifth-graders has shown that the same evaluative and arousal-sedation dimensions used by adults are also detectable in 8- to 11-year-olds, and that the older of these children are more likely to expect positive and arousing outcomes from drinking (Dunn & Goldman, 1996). Following on these earlier studies, the Michigan group examined whether individual differences in positivity of middle childhood expectancies would predict differences in later drinking behavior. Given the developmentally earlier findings linking schema presence to heavier alcohol use in the child's home, we anticipated that children with more positive schemas would begin earlier and progress more quickly into problem use. Newly completed work found that although positive expectancies in middle childhood did not predict onset of drinking, they did predict to a variety of problem indicators, including earlier first binge drinking and earlier drunkenness in the higher positive expectancy group (Jester et al., 2005). Taken together, these early to middle childhood findings indicate that a developmental progression in expectancy structure is taking place substantially before the regular use of alcohol has begun, that this progression is age-graded, that it is to a degree reflective of differences in exposure to heavier versus lighter consumption environments, and that it is anticipatory of greater problem alcohol involvement.

Differences in Alcohol Nonspecific-Risk Structure for Later Disorder Are Present in Early Childhood

Not all of the causal structure for earlier alcohol use and alcohol problems is attributable to alcohol-specific processes. In fact, one of the historically most important findings of the past generation has been the repeated documentation of a link between delinquent and aggressive activity in adolescence and earlier onset of alcohol use, as well as more problematic use (Donovan & Jessor, 1985; Jessor & Jessor, 1977; D. B. Kandel, 1978). Earlier, I provided an overview of the work on problem behavior theory that emphasized the social psychological matrix for these differences. A parallel line of reasoning, driven strongly by a seminal paper by Tarter and colleagues (Tarter, Alterman, & Edwards, 1984), proposed that individual differences in temperament, ostensibly genetically mediated and relating to activity level, low attention span, and behavioral dysregulation are an essential early link in the chain of risk for alcohol use and problems in later childhood and adolescence. The

temperamental substrate, coupled with an environmental structure that facilitates and even presses for the development of these initially neutral temperamental attributes, is hypothesized to culminate in a behavioral adaptation involving antisocial personality, on the one hand, and a deviant peer network as a facilitating context, on the other (Tarter et al., 1999; Zucker, Fitzgerald, et al., 1995). These attributes together are hypothesized to drive both initial alcohol use and the transition into early problem use.

Studies carried out in the early to mid-1990s confirmed these hypotheses cross-sectionally in adolescents (Blackson, 1997; Blackson & Tarter, 1994; Blackson, Tarter, Martin, & Moss, 1994) and in 3- to 5-year-olds from alcoholic and ecologically matched but not alcoholic families (Fitzgerald et al., 1993; Jansen, Fitzgerald, Ham, & Zucker, 1995). In the preschoolers, the outcome proxies were undercontrol measures of impulsivity and a broadband measure of behavior problems (Fitzgerald et al., 1993). Moreover, the highest behavior problem subgroup of children in this study scored higher on the difficult temperament dimensions described by the Tarter group. The difficult temperament children were also more likely to come from families where the alcoholic fathers were lower in socioeconomic status and higher in antisocial comorbidity and had alcohol problems of greater severity and of longer duration (Jansen et al., 1995; Zucker, Ellis, Bingham, & Fitzgerald, 1996).

Over the past decade, the prospective evidence has steadily amassed for these connections, to the point now that six longitudinal studies, two beginning as early as age 3 (Caspi, Moffitt, Newman, & Silva, 1996; Zucker,

Fitzgerald, et al., 2000), have shown a direct link between the early child manifestations of these attributes, specifically behavioral undercontrol and aggressiveness, and AUD and other alcohol problem outcomes in adolescence and early adulthood (Caspi et al., 1996; Masse & Tremblay, 1997; Mayzer, Puttler, Wong, Fitzgerald, & Zucker, 2002, 2003; Mayzer, Wong, Puttler, Fitzgerald, & Zucker, 2001; Zucker, Fitzgerald, et al., 2000). These studies join with two earlier reports of projects beginning in middle childhood (Cloninger, Sigvardsson, & Bohman, 1988; Eron, Huesmann, Dubow, Romanoff, & Yarmel, 1987) with similar childhood markers at baseline and with alcoholism and drunk driving outcomes in adulthood. Another study from the 1990s, the Seattle Social Development Project, replicated these findings into adolescence (Hawkins & Catalano, 1992; Hawkins, Catalano, Kosterman, Abbott, & Hill, 1999). Four of the studies, the Dunedin Health and Development Study (Caspi et al., 1996), the Columbia County Study (Eron et al., 1987), the Seattle Project (Hawkins & Catalano, 1992), and the Montreal Longitudinal Study (Masse & Tremblay, 1997), involved general population samples, and two involved COA samples and matched controls (Cloninger et al., 1988; Mayzer et al., 2001, 2002; Zucker, Fitzgerald, et al., 2000). Table 17.3 summarizes the ages at baseline and follow-up and the baseline behaviors and adolescent/adult outcomes of the study. The level of replication shown across this work must be taken as definitive evidence that a robust relationship exists between early childhood behavior and adult AUD. Combined with the adolescent studies noted earlier, findings indicate that a continuity

Cloninger et al. (1988)	High novelty seeking; low harm avoidance	11	27	Alcoholism

pathway exists from very early childhood to an alcoholism outcome in adulthood.

Equally important, both of the COA studies (Cloninger et al., 1988; Mayzer et al., 2002) as well as four general population studies (Caspi et al., 1996; Hawkins & Catalano, 1992; Hawkins et al., 1999; Kellam, Brown, Rubin, & Ensminger, 1983; Kellam, Ensminger, & Simon, 1980; Werner, 1986) found that a behavioral inhibition/shyness/social fearfulness cluster predicted alcoholism and alcohol problem outcomes in adolescence and early adulthood (Table 17.4). These latter characteristics have only sporadically been reported in the adolescent literature (Kaplan, Martin, & Robins, 1982), but they are consistent with the known adult relationship between Social Phobia and AUD (Kushner, Sher, & Beitman, 1990), and they also have been reported in some historically earlier prospective studies begun in early childhood.

In all of this work, parallel findings are reported from both the COA and the general population studies, suggesting that it is the risk factor(s) rather than the COA status of the sample that is accounting for these relationships. At the same time, the socialization environment is virtually uncharacterized in most of these studies. Thus, it is not possible to determine the degree to which contextual factors may be moderating or mediating the relationship. Moreover, even in the non-COA samples, one cannot automatically assume a more benign environment. In fact, in three of the general population studies reviewed here, the Montreal Longitudinal Study (Masse & Tremblay, 1997), the

Seattle Project (Hawkins & Catalano, 1992), and the Woodlawn Study (Kellam et al., 1980), the study design was deliberately set up to provide a sample of families of low socioeconomic status and high social adversity. Thus, even in the non-COA studies, the level of environmental adversity may have been sufficiently damaging and sufficiently similar to what existed in the alcoholic homes to produce the parallel effects.

A recent report from the Michigan Longitudinal Study suggests that the multifactorial causal structure for AUD extends even more broadly than undercontrol and shyness/social inhibition. Wong, Brower, Fitzgerald, and Zucker (2004) observed a relationship between ratings of sleep problems at ages 3 to 5 and early onset of drug use (alcohol, cigarettes, marijuana, other hard drugs). The relationship remained even when a number of other plausible mediators, including family history of alcoholism and externalizing problems (specifically, attention problems and aggression) were added into the predictive model. In other words, sleep difficulties very early in life appear to be a marker of an independent contributor to early substance involvement. Given that early alcohol use has repeatedly been identified as a proxy for elevated later risk of alcohol dependence, as well as a host of adolescent problems, including injuries, violence, and drunk driving (Gruber, DiClemente, Anderson, & Lodico, 1996), these data support a third risk pathway. Although a self-medication hypothesis and a central dysregulatory deficit hypothesis are both plausible mechanistic explanations for the effect, the

TABLE 17.4 Longitudinal Studies Connecting Early and Middle Childhood Behavior to AUD and Alcohol Problem Outcomes in Adolescence and Adulthood: II. Internalizing Problems

mechanisms undergirding that relationship remain to be identified.

Heterogeneity in the Course of Risk and Heterogeneity of Nonspecific Risk

Although young children who are high in undercontrol present very differently from those with fearfulness and social inhibition, the studies reviewed in the previous section indicate that they have at least one common end point: a higher probability of developing an Alcohol Use Disorder. This seeming anomaly is a clear example of a well-known systems theory concept—equifinality—wherein multiple, sometimes linked and sometimes disparate processes engage in a way that produces a common phenotypic end point (Cicchetti & Rogosch, 1996). The core etiologic questions are, How did they get there, and to what degree will their longer-term developmental trajectories converge or diverge over time? The moderately high correlation observed between externalizing and internalizing problems in childhood (Achenbach & Edelbrock, 1991; Krueger, Caspi, Moffitt, & Silva, 1998) suggests that the pathway of risk is a converging one. Conversely, even a moderately high relationship indicates that in some instances the behavioral syndromes are linked and in some not. The existing comorbidity evidence from developmental studies in childhood suggests that developmental pathways are different when the two syndromes co-occur than when they do not. Thus, Ialongo and colleagues (Ialongo, Edelsohn, Werthamer-Larsson, Crockett, & Kellam, 1996) found that the stability of aggression among first graders strengthened rather than attenuated in the presence of comorbid anxiety, and Wong and colleagues (Wong, Zucker, Fitzgerald, & Puttler, 1999) observed that over the interval from preschool to early adolescence, children with a faster rate of increase in internalizing problems had a slower rate of decrease in externalizing problems.

The strength of these interactive relationships has not yet been evaluated vis-à-vis a substance abuse outcome, but what little comorbidity data there are suggest that the most efficacious model of risk from early childhood to adolescence is an additive one. When externalizing, undercontrolled behavior is present along with depression/anxiety, onset of use is earlier and a later problem outcome is more likely. A good deal of evidence, both direct (Tarter et al., 1999, 2003) and indirect (Sung, Erkanli, Angold, & Costello, 2004), is supportive of this position. Evidence from our own group is also largely confirmatory of this conclusion but indicates that the developmental manifestations of this process are not linear. Support for a continuity

model of process is present only at certain points in development. Furthermore, the process is significantly impacted by the level of adversity in the family, a level of influence that often is not measured.

I illustrate the developmental variation and complexity of the process by briefly summarizing recent work from the Michigan Longitudinal Study (Zucker, Fitzgerald, et al., 2000). This longitudinal family study is following alcoholic men, their spouse, their initially 3- to 5-year-old sons, other siblings, and a suitably matched but nonalcoholic set of contrast families drawn from the same high-risk neighborhoods where the alcoholic families live. *N* for these analyses involved 303 families. All family members were assessed at 3-year intervals beginning when the target boy was 3 to 5 years of age. A person-centered approach was used in examining the joint effects of family adversity and child risk vulnerability over the interval between 3 and 14 years of age.³ The adversity index we used assessed level of family pathology. A summative family psychopathology measure was created that scaled both currency and severity of AUD in each of the parents, as well as the presence/absence of antisocial behavior in each, then added them together (cf. Wong, Zucker, Fitzgerald, & Puttler, 1999; Zucker, Wong, Puttler, & Fitzgerald, 2003). Highest family adversity involved having two parents with currently active alcoholism, or one parent with a comorbid Antisocial Personality Disorder diagnosis, or both. This index, although established by way of parental psychopathology, is an effective proxy for a number of other pertinent indicators of family adversity, including greater conflict, violence, economic difficulty, family crises, other psychiatric comorbidity, and trouble with the law (Zucker, Ellis, Fitzgerald, Bingham, & Sanford, 1996). In addition, on the basis of national Epidemiologic Catchment Area Study alcoholism comorbidity rates (Helzer, Burnam, & McEvoy, 1991) and national familial alcoholism figures (Grant, 2000; Huang, Cerbone, & Gfroerer, 1998), these cutoff criteria would yield a population encompassing slightly less than 1% of U.S. households but approximately 20% of alcoholic families (the severest subset).

The child's initial risk status at age 3 to 5 was described by a global sociobehavioral psychopathology measure that was nationally normed (the Total Behavior Problems scale of the Child Behavior Checklist; Achenbach, 1991). Low risk was defined as being within normal limits on this global index; high risk was defined as being at the 80th per-

³This section is based heavily on two unpublished working papers written by M. Burmeister and the author on the genetics of substance use disorders.

centile or higher on the measure (0.84 SDs above the norm). A 2-by-2 grid was created by crosscutting these dimensions. Initially, *resilient children* were defined as having normal to high adaptation (i.e., low “risk” scores) even though they were living in high-adversity families. The group having normal risk under conditions of low family adversity was labeled *nonchallenged* to emphasize that their behavior was unremarkable, in families with low parent psychopathology that exerted no pressure for deviance and that were more likely to be nurturant and encouraging. The group with high risk (high psychopathology) under conditions of high family adversity was labeled *vulnerable* to emphasize the continuing exposure to family difficulty that took place there (cf. Clark, Lesnick, & Hegedus, 1997), as well as the likely high genetic load for substance use disorder. Other evidence from the study shows that these children had been negatively impacted by this exposure (Wong, Zucker, Fitzgerald, & Puttler, 1999). Finally, those children with high risk (high psychopathology) under conditions of low family adversity were characterized as *troubled* to emphasize that, even without the familial adversity, they still showed a poor behavioral adaptation.

Figure 17.3a shows the trajectory of externalizing problems for each of the groups, and Figure 17.3b shows the trajectory of internalizing problems from preschool to early adolescence. Overall across-age group differences were significant for both externalizing and internalizing problem trajectories. The nonchallenged group sustained the lowest level of externalizing problems over the course of childhood and early adolescence, followed by the resilient group, the troubled group, and the vulnerable group. At all ages, the vulnerable group remained highest in externalizing problems. The figure also shows a consistent pattern of decline in externalizing behavior over childhood, a pattern that is normative for this age range (Loeber, 1982). In addition, there is increasing convergence in the level of externalizing difficulties through middle childhood. At the transition to adolescence, the normative pattern of a developmental shift involving increasing externalizing (aggressive/delinquent/impulsive) behavior (cf. Jessor & Jessor, 1977) is present. The individual-difference data indicate that whereas the resilient children were not distinguishable from their nonchallenged peers as preschoolers, they showed a small but reliably higher level of externalizing problems as they grew older. In other words, a small but detectable convergence with the initially more externalizing two groups starts to become manifest. At the same time, they still occupied an intermediate place, having a lower level of these behaviors than did their vulnerable peers. In addition, the divergence of slopes between ages 9 to 11 and

Figure 17.3 (a) Externalizing symptoms over time in groups differing on risk and adversity. (b) Internalizing symptoms over time in groups differing on risk and adversity. *Source:* “Resilience and Vulnerability among Sons of Alcoholics: Relationship to Developmental Outcomes between Early Childhood and Adolescence” (p. 88), by R. A. Zucker, M. M. Wong, L. I. Puttler, and H. E. Fitzgerald, 2003, in S. Luthar (Ed.), *Resilience and Vulnerability: Adaptation in the Context of Childhood Adversities*, New York: Cambridge University Press. Reprinted with permission.

12 to 14 involved a significant interaction between child individual differences in initial risk and level of family adversity exposure during a period of life when the overall norm is for increasingly deviant and impulsive activity. This interaction had previously been observed cross-sectionally among these children when they were 3 to 5 years of age (Wong, Zucker, Fitzgerald, & Puttler, 1999). The trajectory data indicate the pattern is sustained developmentally; they depict *continuity over time* in group positioning vis-à-vis level of undercontrolled behavior, and the positioning is sustained across the risk-adversity groups even though level of group differentiation varies, as does absolute level of undercontrolled activity.

Figure 17.3b shows the trajectories for internalizing problems; here also the nonchallenged group shows the

lowest level of problems, followed by the resilient group. The troubled group is similar to the vulnerable group. The figure also shows important pattern variations. During preschool and up through the early school years, an identical individual-difference pattern exists. Nonchallenged and resilient children are significantly lower in internalizing symptoms than both the vulnerable and troubled groups, and there are no differences between the resilient and the nonchallenged children. The pattern begins to diverge following second to third grade, and by early adolescence the nonchallenged group is significantly lower than all others, and no differences exist between any of the other three groups. In other words, at this juncture, the resilient children have developed a level of internalizing symptoms that is similar to both the vulnerable and the troubled children's. Here also we tested this group by time interaction with a repeated measures analysis of variance. A significant interaction effect of time and adaptation group indicated that the developmental trajectories of internalizing problems varied differently among the adaptation groups, with three of the four showing a continuity pattern and one a discontinuity pattern.

At a more phenomenological level, the internalizing trajectory pattern of the resilient group implies that a weathering process has been taking place, wherein an initially happier adaptation gives way to the sustained exposure to an adverse, more conflictual environment involving more family stress and disruption. The result, by early adolescence, is that the level of internalizing behavior for this group is indistinguishable from that of the initially more troubled and vulnerable children. These data provide a poignant illustration of how the shift from normal to pathological adaptation may take place under circumstances of sustained adversity. Recall, however, that this shift occurs only in the more covert, internalizing behavior domain; the more obvious externalizing behavior differences remain, with the resilient children sustaining a pattern that differentiates them from their vulnerable and troubled peers.

These patterns of trajectory variation in both externalizing and internalizing problems also illustrate the nonlinearity of risk development over time. Moreover, other work by our group (Fuller et al., 2003) indicates that the salience of different aspects of the parental environment varies developmentally. Level of child externalizing behavior (aggressiveness) in the preschool years was predicted by marital aggression/conflict as well as parental alcoholism but not by direct punishment; in middle childhood, the child outcome was predicted only by direct punishment.

The trajectory variations reflect more than just differences in nonspecific risk over time. They also are proxies for

differences in probability of eventual problem drinking, other problem behavior, and alcohol dependence (Ellickson, Tucker, & Klein, 2003; Grant & Dawson, 1997; Pederson & Skrandal, 1998). In the Michigan study, Mayzer, Puttler, Wong, Fitzgerald, and Zucker (2002, 2003) have already confirmed the first step in this chain of effect by showing that higher levels of early externalizing and internalizing behavior are predictive of both early onset of drinking and higher levels of externalizing and internalizing behavior and delinquent activity in adolescence. On both these grounds, and given what is known about early onset of alcohol use as a precursive marker (Gruber et al., 1996), these results indicate that the children identified as vulnerable are at highest risk for a later AUD outcome, the nonchallenged group is at lowest risk, and the resilient group is at intermediary risk, in part because of the increasing experience of internalizing problems as they move into adolescence.

More generally, given what has already been established about the utility of the externalizing and internalizing behavior as proxy indicators of alcohol problems and elevated risk for later AUD, these findings emphasize the importance of characterizing both familial risk and individual risk in understanding the variability of pathways into problem alcohol use (also see Garnier & Stein, 2002). When individual vulnerability is present early, even a nonchallenging family environment is insufficient to moderate the child's vulnerability. Conversely, from the perspective of risk for externalizing problems, a subset of COAs moves through childhood relatively trouble-free and another subset, showing early risk, is the highest-risk vulnerable subgroup.

This pattern is tempered to a considerable degree for internalizing risk. For one subgroup of young COAs, the resilient children, their early behavior indicates that they are relatively free of sadness, anxiety, depression, and worry. Exposure to the adversity of an actively alcoholic home with its attendant strain and conflict (Loukas, Zucker, Fitzgerald, & Krull, 2003) leads to a gradual degradation of their affective status, such that by the time adolescence is reached, their level of internal trouble is equivalent to that of their more obviously less fortunate peers (the troubled and vulnerable children).

One caveat is needed to temper these conclusions: The evidence from both the Loukas et al. (2003) and Fuller et al. (2003) studies indicates that the family effects are partially attributable to an active environment, with level of parental conflict as well as type of conflict (marital aggression/conflict at preschool, direct punishment in middle school) influencing child risk. However, these studies cannot disentangle the nesting of high-child risk in high-biological-risk families. Vulnerable children are more likely to come from high-

adversity families, and the correlation of family and child risk that is present leaves open the possibility that the exacerbation of behavioral problems that appears to be a socialization effect is actually the result of indirect genetic effects. The variable network we currently have at our disposal makes it impossible to evaluate these two plausible and not necessarily competing hypotheses about mechanism.

Heterogeneity of Alcohol-Specific Risk: Prolegomenon to Phenotypic Heterogeneity of Alcohol Use Disorder

The work presented so far has focused on precursive risk factors that are nonspecific to an alcohol problem or AUD outcome. However, parallel evidence for heterogeneity has been described by Schulenberg and colleagues for one of the core end points of this chapter, problem alcohol use. Drawing on national Monitoring the Future panel data on consumption, Schulenberg, O'Malley, Bachman, Wadsworth, and Johnston (1996) examined patterning of problem alcohol use over the age 18 to 24 interval, the period where peak rates of use and problems are present. The consumption measure they used was binge drinking (5 or more drinks in a row), the index already described earlier. The problem indicator was *frequent* bingeing, defined as two or more occasions in the past 2 weeks. Six distinct trajectories of binge drinking were identified that accounted for over 90% of the sample and that included stable patterns (never, rare, and chronic) as well as patterns of cross-temporal variation (decreased, increased, and fling; see Figure 17.4). Women were overrepresented in the never group and underrepresented in the chronic and increased groups. Binge trajectory differences were related to concomitant variation in problems with alcohol, attitudes about heavy drinking, time spent with heavy-drinking peers, and extent of illicit drug involvement. In other words, a pattern of behaviors was being indexed by the binge variation, but it encompassed a substantially larger set of characteristics that shifted (or remained stable) along with the drinking. Furthermore, being lower in conventionality and self-efficacy and drinking to get drunk were senior-year risk factors for membership in the increased trajectory group, and higher self-efficacy and lower motivation pertaining to drinking to get drunk were protective factors against involvement in the continued bingeing trajectory for initially frequent binge drinkers (Schulenberg, Wadsworth, O'Malley, Bachman, & Johnston, 1996). This study was the first in this age range to demonstrate the importance of distinguishing trajectory classes. When one looks at the population "trajectory" (the total group) in Figure 17.4, it is evident how misleading a characterization of developmental process is

Figure 17.4 Mean binge drinking scores of 5 or more drinks in a row in the past 2 weeks by binge drinking trajectory. Reprinted with permission from "Getting Drunk and Growing up: Trajectories of Frequent Binge Drinking during the Transition to Early Adulthood," by J. Schulenberg, P. M. O'Malley, J. G. Bachman, K. N. Wadsworth, and L. D. Johnston, *Journal of Studies on Alcohol*, 57, pp. 289–304, 1996. Copyright by Alcohol Research Documentation, Inc., Rutgers Center of Alcohol Studies, Piscataway, NJ, 08854.

conveyed by using population means. At the same time, an essential empirical as well as prevention-related question still to be answered is: What characteristics prior to age 18 predict trajectory variation? The answer to this must remain equivocal because the MTF database provides information only on essentially contemporaneous factors in late adolescence that predict later patterning. This question is an essential one for future studies to address.

At this intermediary point in the chapter, a summary observation is in order about the level of discourse so far. From the vantage point of the developmental map outlined earlier, the variation we have so far addressed operates at the second surface, the envelope of behavioral risk and symptomatology, and to some degree the first surface (family and subcultural variation). Although such variation is at the microlevel from the standpoint of societal and environmental structure, it is at the macrolevel from the vantage point of variability assessed lower down in the network. As we address familial variation along with variation in undercontrol/aggression, internalizing behavior, and alcohol using behavior, it needs to be kept in mind that each of these sources of variation may in turn be disaggregated into component segments. Determination of what the active ingredients are in a complete model of the development of risk and disorder needs ultimately to identify what the most useful levels of specificity are, what the critical

variables are at those levels, and what the critical across-level relationships are. This question is not yet capable of being answered, but it continually needs to be posed and plausible core candidate variables need to be put forth and evaluated.

Heterogeneity of Alcohol Use Disorder and Variations in Course of the Disorder/Phenotype

The developmental focus of the etiologic work on onset of drinking and drinking problems leads naturally to an interest in change, and increasingly has led investigators in this field to the utilization of newer statistical methods to analyze change and identify individuals with different patterns of growth over time (Collins & Horn, 1991; Muthén and Muthén, 2000). This focus has been on growth and trajectories of both nonspecific risk and alcohol problems/symptomatology. In the two studies we reviewed in the prior section, along with a host of others (cf. D. B. Kandel, 1978; Zucker, Fitzgerald, et al., 1995), one problem use trajectory emerges that is characterized by elevated child problems prior to adolescence, along with a damaged socialization environment. In the two studies just reviewed, both the vulnerable group trajectory and the MTF chronic group fit this pattern. The residual group (or groups) isolated in earlier work has typically been less well defined, and the more recent and more precise analytic work gives some clues about why this might be. If more developmental variability exists in those lower-risk, lower-symptomatology subgroups, as is the case for the resilient group in the Michigan study and for the increasing, decreasing, and fling groups in the MTF study, then less differentiating analyses will more often merge them, sometimes identifying them as one "other" group and sometimes identifying more than one.

In contrast to the work on youth and early adulthood, efforts to characterize course in adulthood started not from a developmental but from a clinical vantage point. Here the intent historically has been to find coherent symptomatic groupings that would parse the clinical symptomatology and history in a way that would allow the clinician to evaluate severity, anticipate/predict course, and, it was hoped, also suggest subtype-specific treatments that would be more effective than a one-size-fits-all classification scheme. Babor's (1996) historical review of the classification/typology literature has been able to identify type classifications as far back as 1850. He observed that the English physician

the desire to drink occurs suddenly, but the disease rarely progresses beyond irregular intoxication. The periodic form is characterized by a pattern of binge drinking that becomes progressively more severe and damaging. In the chronic form, the desire for alcohol stimulation becomes an overwhelming preoccupation that precipitates constant alcohol consumption. (p. 7)

Although mention of drinking consequences was missing from Carpenter's acute category, the acute form maps reasonably well onto the *DSM-IV* classification of alcohol abuse. Carpenter's periodic and chronic forms bear some resemblance to Cloninger, Bohman, and Sigvardsson (1981) milieu-limited and male-limited types, which have more recently been designated as Type I and Type II alcoholism, respectively (Cloninger, 1987).

Babor's (1996) review concluded that the major empirical classification studies repeatedly rediscover these two types, which he more generically labels as Apollonian and Dionysian. The former is characterized by later onset of alcohol dependence, a slower disease course, fewer social complications, less psychological impairment, and a better prognosis, and the latter is characterized by early onset, physical aggression, more severe symptomatology, a denser positive family history (suggesting a stronger genetic basis for the disorder), and more personality disturbance (p. 13). Newer studies using factor-analytic and cluster-analytic techniques continue to document the utility of this two-category scheme, but periodically other subtypes show up. Thus, Del Boca and Hesselbrock (1996) observed in a cluster analysis of a heterogeneous inpatient population that another nonantisocial subtype could be identified that was heavily comorbid with depression and anxiety and was twice as common in women as in men (also see Ball, 1996; Windle & Scheidt, 2004).

In coming to a conclusion about how much differentiated variation exists in the adult course of AUD, it is essential to keep in mind that the use of treatment samples to establish typologies is inherently a biased activity, given the restrictions in range of variation, severity, and comorbidity that are found in such subject populations. As far back as 1946, Berkson noted the bias in such samples. They are restricted to more severe and nonremitting cases and also may be socioeconomically biased, given who ends up in large public institutions. It is on these grounds that both the earlier Epidemiologic Catchment Area data set (Helzer et al., 1991; Regier et al., 1990) and the more recent National Comorbidity Study (Kessler et al., 1994, 1997) are so important in understanding the manner in which comorbidity and course are linked over time. Working from these

[William] Carpenter proposed three categories of oinomania [wine mania]: acute, periodic, and chronic. In the acute form

databases, in a series of earlier papers (Zucker, 1987, 1994; Zucker, Chermack, & Curran, 2000) I have described six subtypes that account for the observed epidemiologic and comorbid variation. The types were established based on the epidemiologic evidence of major differences in developmental trajectory as well as differences in adult function, comorbidity, course, and prognosis for the different subtypes, and although several of them were proposed solely on the basis of a careful literature review rather than typological analysis, recent efforts to characterize this heterogeneity continue to support their validity (Hasin, Paykin, & Endicott, 2001; Windle & Scheidt, 2004).

Figure 17.5 provides graphic representations of the trajectories of the different types. Three are characterized by way of their association with specific forms of psychiatric comorbidity (Figure 17.5a); the other three, as a group, are differentiated by their *lack of significant comorbidity* (Figure 17.5b). One of the comorbid forms, the one most commonly described, is the *antisocial alcoholic* type. This subtype has already been described from the perspective of emerging adolescent problem behavior, but it has not been given a clinical label by adolescence researchers (Weber, Graham, Hansen, Flay, & Anderson, 1989). This is Babor's Dionysian type, also Cloninger's male-limited

(Type II) group, and involves a continuity pathway, a co-association of long standing between alcohol problems and antisocial behavior in its developmentally progressing forms (Zucker, Ellis, Bingham, et al., 1996). The antisocial behavior first shows as conduct problems, later emerges into delinquent activity, and ultimately shows as Antisocial Personality Disorder. The antisocial behavior is a central part of the emergence of the alcoholism, and the alcohol problems and alcoholism are an essential piece in the emergence of the antisocial adaptation (see Zucker, Ellis, Bingham, et al., 1996, for a fuller description of this type). A second type, *developmentally limited alcoholism*, likewise involves a comorbid antisocial connection, but the Conduct Disorder is stage-limited (i.e., this is the stage-specific delinquent and impulsive activity of the adolescent problem behavior syndrome that was described earlier; cf. Donovan & Jessor, 1985). The antisociality is coupled with the problem alcohol use endemic to adolescence. Howard Blane (1979) called attention to it more than a generation ago without giving it a formal "alcoholism" label. (He called it "frequent heavy drinking.") The third type involves the emergence in childhood and adolescence of internalizing symptomatology in high-risk populations (Colder & Chassin, 1993; Earls, Reich, Jung, & Cloninger, 1988; Rolf, Johnson, Israel, Baldwin, & Chandra, 1988; Sher, Walitzer, Wood, & Brent, 1991), but it is linked to a trajectory of severe and sustained alcohol-related difficulty only in adulthood. This third pattern, termed *negative affect alcoholism*, is more common among women (Del Boca & Hesselbrock, 1996; Turnbull & Gombert, 1990) and has also been tied to the special role demands that women face (Wilksnack, Klassen, Schur, & Wilksnack, 1991), as well as to the influence of genetic factors common to both Major Depression and alcoholism (Kendler, Heath, Neale, Kessler, & Eaves, 1992; Merikangas, Leckman, Prusoff, Pauls, & Weissman, 1985).

In contrast to the comorbid subtypes, the trajectories schematically presented in Figure 17.5b depict a set of alcoholisms that have no clearly demarcated childhood antecedents. They involve sustained alcohol intake, which leads to severe alcohol-related symptomatology. No other behavioral covariation is known to have linkages to their onset, and they are identifiable more by their drinking-related consequences than their nondrinking etiology. This is the type that is most often viewed as the pure example of alcoholism as an addictive disorder. It is almost certainly driven by alcohol-specific vulnerabilities, including a lower sensitivity to ethanol's intoxicating effects (Schuckit et al., 2001; Schuckit, Smith, & Tipp, 1997) and a greater subjective experience of activation and

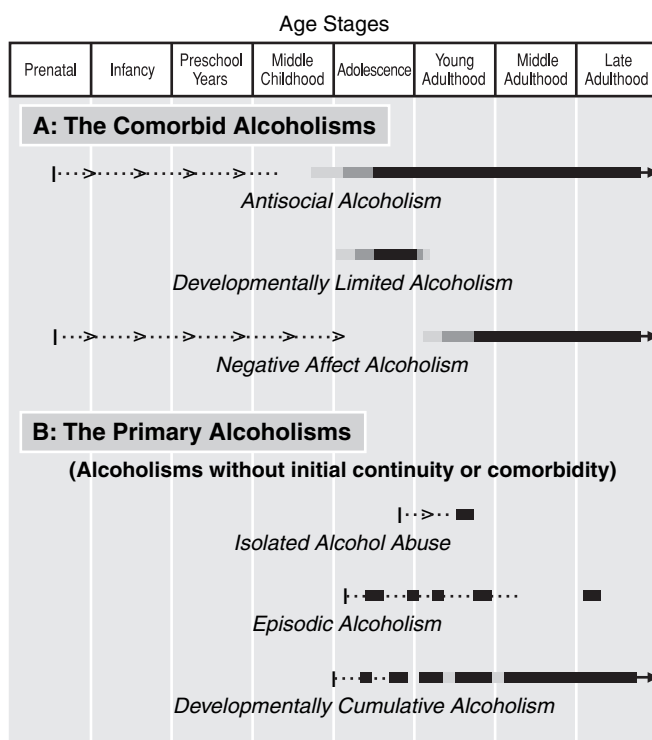

Figure 17.5 Course of the comorbid alcoholisms and the primary alcoholisms.

energy that makes consumption both more reinforcing and less aversive (Newlin & Thomson, 1990). In its more extreme form, a strongly addictive disorder emerges over time (Hill, 1992). A secondary hypothesis is that this trajectory and the other noncomorbid forms are driven by the presence of elevated environmental stress, occurring in a social context that provides a support and value structure for alcohol as the drug of choice for tension reduction. Under circumstances of nonsustained stress (e.g., immediately preceding or following the breakup of a marriage; cf. Cahalan, 1970), *isolated abuse* may occur. Under circumstances where the stress is recurring (e.g., times of heightened stress related to periodic job layoffs; cf. Brenner, 1973), or for those in intermittently high-stress occupations, the symptomatology becomes *episodic*. For those whose contextual and individual vulnerability match is greatest, the alcohol-seeking behavior eventually moves into a chronic adaptation. This latter trajectory has been termed *developmentally cumulative alcoholism*. There are obvious parallels between these latter three trajectories and the developmentally limited but antisocially comorbid pattern of adolescence. Although the form of all four of these types is similar, for the developmentally limited pattern, individual-level etiologic risk factors have already been identified, but the onset and termination of the disorder is driven by non-individual-level contextual factors to which the individual responds. Nonresponsivity (i.e., the perseverance of the high consumption level in the face of increasing social stigma and penalty) is what differentiates the developmentally cumulative pattern from both the developmentally limited and the episodic pattern. This may also be the case for the episodic and developmentally cumulative variants; in fact, both Schuckit and Moos and their colleagues (Moos, Brennan, & Schutte, 1998; Schuckit, 1988, 1994) have addressed this issue. But at the moment, their causal structure has been less well charted.

THE OTHER HALF OF THE STORY: ETIOLOGY FROM A NEUROBIOLOGICAL PERSPECTIVE

The review thus far has focused primarily on the environmental and behavioral segments of the risk matrix. In this and the following section, I review genetic and other neurobiological contributors to this matrix.⁴

Alcoholism as a Genetic Disorder

Alcoholism is a complex phenotype; the previous two sections on heterogeneity of risk and disorder drive this point home. The fact that the phenotype's expression is dependent on the presence of an environmental object (ethanol) suggests that environmental factors play a significant role in etiology, but the evidence for a genetic contribution to alcoholism risk is also indisputable. Evidence from family, adoption, twin, and cross-fostering studies all support this conclusion. A summary report by McGue (1994) of seven twin studies concluded that heritability estimates range from 40% to 60% for males and from 0 to 58% for females. However, other work with larger samples indicates that heritability of female alcoholism is approximately the same as it is for men (Kendler, Neale, Heath, Kessler, & Eaves, 1994; Nurnberger et al., 2004).

It is important to note that the widely observed variability in heritability effects is not evidence indicating weakness of the effect. Rather, a characteristic of multifactorial phenotypes such as alcoholism is that the variability in estimation is both a function of the way the phenotype (such as diagnosis) is measured, as well as the variability in the population (Falconer & MacKay, 1996). In turn, the population variability is itself a function of environmental exposure (e.g., alcohol availability), age structure, and population genetic variations. The latter determine the allele frequency of a particular gene, which in turn determines the degree to which the active variant is or is not present; population-specific environmental variability interacts with that in determining whether a particular gene will or will not be expressed.

The heritability studies point up four other aspects of the genetic etiology of the disorder:

1. Alcohol dependence and alcohol abuse are not unequivocally the same phenotype; that is, they may be not just indicators that differentiate severity but rather differentiable phenotypes. Recent epidemiologic data supporting this view show that approximately a third of the alcohol dependence population do not also meet criteria for abuse (Hasin & Grant, 2004). That is, one may have physiological dependence without ever having gone through an abuse phase involving the adverse, usually social complications that are an essential part of the category. Differences in heritability rates have generally been found for the two categories, with alcohol dependence being the more heritable form (Kaij, 1960; Pickens et al., 1991). But the dialogue remains active both in the genetic and the epidemiologic literature (Grant, 1996;

⁴ See note 3.

Hasin & Grant, 2004; Nurnberger et al., 2004; Ridenour et al., 2003; Schuckit & Smith, 2001). This is an essential issue that needs clarification.

2. It is well-known from the epidemiologic literature that other substance use disorders assort in alcoholic families along with alcoholism, and the more severe Type II/Dionysian form commonly includes comorbid other drug use. This phenomenon is consistent with genetic studies indicating that a large portion of the heritable variance for substance use disorders is not drug-specific, but is shared across drugs of abuse (Kendler, Jacobson, Prescott, & Neale, 2003a; Kreek, Nielsen, & La Forge, 2004; Krueger et al., 2002; Tsuang et al., 1998).
3. The heritability studies also parse the non-drug-specific heritability pathway in another way. Alcoholism is frequently comorbid with other nondrug psychiatric disorders. This phenomenon has been observed in the epidemiologic literature (Helzer et al., 1991; Kessler et al., 1997) and in the trajectory/subtype literature,

and it has already been discussed in early portions of the chapter. What is less often articulated is that the comorbidity itself can be differentiated by content into two clusters, one involving externalizing disorders of undercontrol (Attention-Deficit/Hyperactivity Disorder and Antisocial Personality Disorder), the other involving internalizing/negative affectivity symptomatology (anxiety, depression). Recent family and twin studies indicate that *heritability of AUD is also primarily through these non-alcohol-specific externalizing and internalizing pathways* (Kendler, Prescott, Myers, & Neale, 2003b; Nurnberger et al., 2004). This work, not yet part of the mainstream etiologic literature, indicates significant convergence with the findings on early behavioral risk indicators of later AUD reviewed in an earlier part of this chapter.

Figure 17.6 provides a summary of the core Kendler et al. (2003b) findings. It shows that the strongest heritable pathway is through a common externalizing factor,

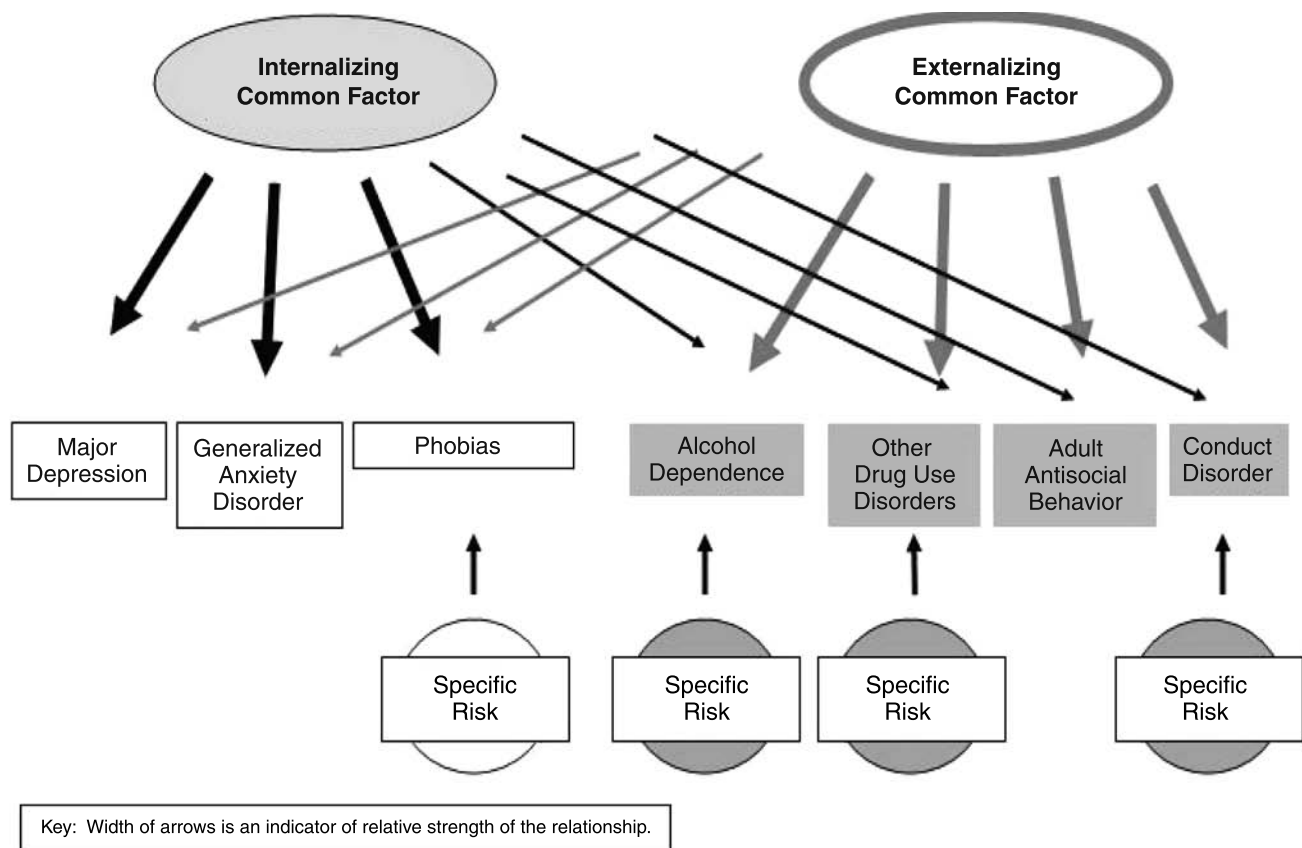

Figure 17.6 Structure of common and disorder-specific genetic risk for common psychiatric and substance use disorders. *Source:* Based on Figures 1 and 3 in “The Structure of Genetic and Environmental Risk Factors for Common Psychiatric and Substance Use Disorders in Men and Women,” by K. S. Kendler, C. A. Prescott, J. Myers, and M. C. Neale, 2003, *Archives of General Psychiatry*, 60, pp. 929–937, and an earlier version of this model by J. Lappalainen.

with a secondary pathway through an internalizing common genetic factor (also see point 4). Each of these factors are almost certainly polygenic traits.

4. Also as shown in Figure 17.6, the Kendler et al. (2003b) analysis indicates that some of the genetic variance for alcohol dependence is disorder-specific. Although their study was not designed to identify the mechanisms and genes that account for this specific variance, a significant body of other work has identified a few of the component pieces that appear to be part of the process.

The most robust genetic markers are variants involved in the metabolism of alcohol—specifically involving aldehyde dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH). The two candidate genes that protect against heavy drinking are the functional genetic variants of alcohol dehydrogenase that exhibit high alcohol oxidizing activity (ADH) and the genetic variant of aldehyde dehydrogenase (ALDH2) that exhibits low acetaldehyde oxidizing activity (Li, 2000). The ALDH2 variant is common in some Asian populations. Those who have it experience a flushing reaction, headache, palpitations, dizziness, and nausea after consuming alcohol. The aversive experience appears to be protective in the populations where that variant exists (Thomasson, Crabb, Eadenberg, & Li, 1993). However, the low prevalence of the ALDH2 deficiency in individuals of European and African ancestry results in very low explanatory power for the U.S. population. High ADH activity is associated with a similarly unpleasant set of symptoms following drinking; here the genetic variants involving the ADH2² and ADH3¹ alleles appear to be protective (Thomasson et al., 1993). At the same time, consistent with a complex genetic model, a cross-national study by Reich and Li (1994) observed that even though Koreans have a relatively high rate of ALDH2 deficiency, alcoholism rates are very high in this population, suggesting that cultural influences may sometimes override the impact of the biological feedback system.

Beyond the genetic variants involved in alcohol metabolism pathways, a number of plausible candidate genes have been identified that may contribute to etiology, but studies are not uniformly confirmatory of a link either to alcoholism or to some intermediary trait such as externalizing or internalizing behavior. Moreover, mechanisms of action are only partially understood at best. Of these, genes involved in regulation of the serotonergic system have received the largest amount of attention in the past generation. Serotonin (5HT) is generally considered to operate as a regulator, with increased 5HT function operating to inhibit behavior (Lucki, 1998). Thus, genes involved in the system's operation should

show some relationship to impulsivity and to the externalizing/undercontrol system. Genetic variants of tryptophan hydroxylase (TPH), the rate-limiting enzyme of the biosynthesis of 5HT, have been associated with anger-related traits (New et al., 1998) and suicide (Turecki et al., 2001). Genetic variants in monoamine oxidase A (the primary enzyme for 5HT catabolism), specifically involving the MAOA promoter, have been associated with impulsive aggression, as well as alcohol-related traits (Brunner, Nelen, Breakefield, Ropers, & van Oost, 1993; Manuck, Flory, Ferrell, Mann, Muldoon, 2000; Schmidt et al., 2000), antisocial alcoholism (Vanyukov, Moss, Yu, Tarter, & Deka, 1995), and impulsive antisocial behavior when in interaction with the presence of childhood maltreatment (Caspi et al., 2002). The 5HT1B receptor has been linked with antisocial alcoholism in humans (Lappalainen et al., 1998) and with increased impulsive aggression in mice (Saudou et al., 1994). Lesch et al. (1996) reported on another gene in the 5HT system that also has potential relevance, namely 5HTTLPR, the promoter for the serotonin transporter. They observed that two common allelic forms of the promoter were associated with variation in neuroticism score, a general index of negative affectivity and emotionality. Since that time, the literature of over a dozen replication attempts has been evenly divided between replications and nonreplications. More than 100 publications have since also reported association with aggression, suicidality, and depression (see Stoltenberg & Burmeister, 2000 for a detailed review). Again, however, none of these studies has been consistently replicated. Although this may be due to lack of power, it also is quite possible that the correct underlying phenotype has not yet been identified, in which case the targeted phenotype would at best be an imprecise indicator of the correct one. More generally, the uncertain relevance of this gene, illustrated by the equivocal findings, indicates the relative infancy of the field, although the burgeoning of genotyping technology, allowing fine-grained genome-wide scans at ever decreasing cost, suggests that this situation will become much more resolved in the next 5 to 10 years.

Other candidate genes beyond the serotonin system have also been put forward as plausible candidates because of a direct connection to alcoholism, because of a demonstrated relationship to intermediate traits subsumable under the externalizing/undercontrol or internalizing/negative affectivity, or because of a known relationship to an intermediate trait (e.g., P300) or behavioral phenotype (e.g., smoking) that has separately been etiologically linked to AUD. I provide a brief laundry list in Table 17.5.

The diversity of potential pathways to the AUD end point that is implied in this list underscores four points that are taken for granted by geneticists but that are less com-

TABLE 17.5 Other Candidate Genes with a Potential Causal Relationship to Alcoholism

Locus Symbol	Variant	Gene Name and Description	Evidence in Literature	Citation
SLC6A3	rs27072; promoter repeat	DAT; dopamine transporter	Smoking; ADHD; alcohol withdrawal, Bipolar Disorder	Waldman et al. (1998)
DRD4	1–10 copies of 48 bp/16 aa-521 C/T	Dopamine receptor D4; exon 3 coding repeat in C-terminal domain; promoter SNP	ADHD, possibly novelty seeking	Faraone, Doyle, Mick, & Biederman (2001)
DAT1	G2319A SNP	Dopamine transporter in the 3' untranslated region	Increased risk for alcoholism	Ueno et al. (1999)
BDNF	Val66Met	Brain-derived neurotrophic factor; Met lower BDNF activity	Bipolar Disorder, neuroticism	Sklar et al. (2002)
COMPT	Val158Met	Catechol-O-methyltransferase; enzyme activity variant	Differentiates late-onset alcoholism from early, although evidence mixed	Tiihonen et al. (1999); Wang et al. (2001)
GABRA2	3 SNPs	GABA alpha 2 subunit; haplotype association	Alcoholism, brain EEG (P300)	Sander et al. (1999)
GABRA6	3 locus haplotypes	GABA _A receptor subunit genes	Alcoholism	Radel et al. (2005)
CYP2E1	1D	Regulatory (expression)	Alcohol, nicotine	Hayashi et al. (1991)

Note: See text for description of genes involved in alcohol metabolism and in regulation of the serotonergic system.

monly appreciated by the behavioral science community. One is that the final common pathway for AUD not only is multifactorial, but also probably includes variables that account for small amounts of variance that make their detection difficult. Thus, studies with low statistical power will be limited in their ability to uncover them, and the etiologic models they create will be underspecified.

Second, the pathway from genetic variation to phenotype is almost certainly indirect, involving a multistage process. The three-step case, from genetic variation to alcohol metabolism to alcoholism, is only the simplest case scenario, and it involves no motivational (reward), appetitive (drug sensitivity, craving), or cognitive (expectancy) mechanisms. Pathways through impulsivity and emotionality involve at least another step in this chain of effect and would suggest that several additional steps are also part of the sequence leading to the end point addictive disorder. Gene-environment interactions, especially those that are developmentally dependent, almost certainly ensure the multistage nature of these sequences (cf. Caspi et al., 2002).

The third point follows from the second point, namely, that intermediate processes are often not going to be visible and detectable at the behavioral level.

Fourth, genes have dual functions: One is a template function, which allows them to replicate with a very high degree of fidelity over time and across generations. They also have a transcriptional function that determines structure and function at the cellular level and at the level of

brain and ultimately also determines the phenotype. The transcriptional function is the one that is highly regulated, and this regulation is susceptible to environmental input (variation; E. R. Kandel, 1998). Environmental experiences such as stress, arousal, learning, and social interaction impact the brain either directly, through changes in the development of neural networks, or through the production of hormones that alter their development. Thus, the brain is the playing field on which gene-environment interactions ultimately take place. All of these observations are implicit in the schematic model presented in Figure 17.2 at the beginning of this chapter, but the details of the bottom-up flow-through process were only briefly touched on at that point.

Intermediate-Level Etiology in Brain

Given the interplay of these mechanisms in brain, two different lines of investigation have worked at delineating the structures and neural circuitry that are involved in the development of alcoholic etiology.⁵ One, more than a century old with a history in both neuropathology and neuropsychology, has worked to identify those structures crucial to

⁵This section is based heavily on unpublished working papers and ongoing collaborations between Joel T. Nigg, Mary M. Heitzeg, Jon-Kar Zubieta, and the author.

the action of ethanol on the brain. Up until a generation ago, this work focused on brain impairments from high alcohol dosing over long periods of time, as found in chronic alcoholism (see the reviews by Ron, 1987; Victor, Adams, & Collins, 1971). This work has implicated the mesocorticolimbic dopamine system, including the nucleus accumbens, amygdala, hippocampus, and prefrontal cortex, as the system where the pharmacological actions of ethanol converge to produce their reinforcing effects (see review in Weiss & Porrino, 2002).

Using this as baseline evidence for site of action, a second line of investigation in more recent years has asked whether any of these sites has a predispositional vulnerability both to impairment and to alcohol-seeking behavior. At the neurocognitive level, a number of constructs have been identified as important to risk. Executive functioning entails the ability to regulate behavior to context and to maintain a goal set; it relies on multiple constituent functions (Miyake et al., 2000). This is a multicomponent construct, including such elements as response suppression/inhibition (the ability to strategically suppress a prepotent or prepared motor response), working memory (itself multicomponential), set shifting, and interference control (Pennington & Ozonoff, 1996). These capacities are represented to a large degree in parallel frontal-subcortical-thalamic neural loops; important structures include right inferior frontal cortex-to-basal ganglia (response inhibition; Aron, Fletcher, Bullmore, Sahakian, & Robbins, 2003), dorsolateral prefrontal cortex and associated structures (working memory; Klingberg, Forssberg, & Westerberg, 2002; Marshuetz, Smith, Jonides, DeGutis, & Chenevert, 2000; Thomas et al., 1999), and anterior cingulate cortex. These networks are heavily subserved by catecholamine innervation. To the extent that they translate directly to behavioral differences, they have relevance to a spectrum of activities that elevate or dampen risk. They relate to wisdom in choice of peers, understanding of the importance of context to appropriate drinking behavior, ability to desist when encouraged to drink or encouraged to continue drinking under circumstances that indicate drinking consequences, such as increasing intoxication, and the ability to get to work or school the next day and adequately function—behaviors that may be costly in the long term.

Extensive theory as far back as a generation ago (Tarter, Alterman, & Edwards, 1985) would link aspects of executive control with alcoholism risk, although data to support that link are mixed (Finn, Mazas, Justus, & Steinmetz, 2002; Giancola & Moss, 1998; Peterson, Finn, & Pihl, 1992; Tarter et al., 1999). More recent work (Nigg, Wong, et al., 2005) suggests that the risk element here is primarily re-

lated to response inhibition. In addition, Finn and colleagues (Finn, Justus, Mazas, & Steinmetz, 1999) have theorized that auditory working memory moderates temperamental risk for alcoholism. Other neuropsychological theories of individual vulnerability to alcoholism are numerous, but a great many are at a level of low specificity (cf. Tarter et al., 2003), thus making it impossible, on the one hand, to link findings to activation of specific brain regions/functions and, on the other, to develop specific testable models that can be confirmed or disconfirmed and that will allow for the development of a systematic knowledge base. For these reasons, it is essential to develop (and test) models at a high level of specificity. In particular, in addition to response suppression and working memory from the executive domain, the role of right-lateralized visual-spatial functioning as a correlate of substance use risk (Schandler, Thomas, & Cohen, 1995) is of great current interest. Although this correlation is often observed, a process explanation of why spatial weakness would cause maladjustment may have to rely on appeal to related right hemisphere processes, most notably social information processing. Conceivably, a social information-processing weakness may mediate any observed visual-spatial deficit effects on drinking problems in early adulthood.

Closely intersecting with these processes is the domain of motivation, and reward responsivity in particular. Reward response involves dopaminergic pathways in the mesocortical and mesolimbic pathways that are closely related to those involved in executive control. The literature clearly indicates that executive and reward response mutually influence one another (Nigg, 2000; Rothbart & Bates, 1998) both in development and dynamically. Extensive data suggest that at both the behavioral and the neural level, substance use problems are associated with a dysregulation of reward responsivity, such that the subcortical, involuntary elements (subserved by limbic and striatal circuitry) are overresponding to salient drug-associated stimuli, and the normal cortical control (via frontal circuitry) over this response is impaired or inhibited, leading to excessive risk-taking behavior (Goldstein & Volkow, 2002; Jentsch & Taylor, 1999; Rosenkranz & Grace, 2001). Furthermore, there is preliminary evidence for a dysregulation of reward-related circuitry in at-risk populations before alcohol and illicit drug use occurs (Heitzeg, Zucker, & Zubieta, 2003).

Developmental Significance of Neural Models in Late Adolescence

At the same developmental time during which a major buildup of alcohol use and alcohol problem behavior is tak-

ing place, neural alterations in the frontal executive and reward systems involved in impulse and emotion regulation are occurring. The dorsolateral prefrontal cortex (important to executive functioning as well as motivation) is one of the last brain regions to mature, with myelogenesis continuing at least until early adolescence (Fuster, 1997) and potentially all the way into early adulthood (Benes, 2001; Gogtay et al., 2004). Progressive increases in the white matter of this region have been shown during childhood and adolescence (Reiss, Abrams, Singer, Ross, & Denckla, 1996). These developmental changes directly impact impulse and emotion regulation. It is known that throughout childhood, there are developmental gains in the ability to suppress or inhibit prepotent responses and the ability to suppress irrelevant information (Brainerd & Reyna, 1993; Casey, Tottenham, & Fossella, 2002; Diamond, 1990). Social and emotional skills, such as the ability to discriminate emotional facial expressions, also develop throughout childhood and early adolescence (Kolb, Wilson, & Taylor, 1992), with associated changes in amygdala responsivity (Thomas et al., 2001). Furthermore, during the interval from childhood through adolescence, the prefrontal cortex gains greater efficiency in its inhibitory control over the amygdala and other limbic structures involved in emotion and reward response (Damasio, 1998; Hariri, Bookheimer, & Mazziotta, 2000; Killgore, Oki, & Yurgelun-Todd, 2001). In addition to these structural brain changes, both human and animal studies indicate that there is an alteration in mesocorticolimbic dopamine systems in the adolescent brain (reviewed in Spear, 2002). Dopamine input to the prefrontal cortex peaks during adolescence in nonhuman primates (Rosenberg & Lewis, 1994) and rats (Kalsbeek, Voorn, Buijs, Pool, & Uylings, 1988), and dopamine binding, primarily in the striatum but also in the nucleus accumbens (important for reward responsivity), also peaks during adolescence (Seeman et al., 1987). Understanding, at the neural activation level, how these mechanisms operate is crucial to a full explanation of individual risk using neurocognitive and neurobehavioral models.

The developmental significance of these changes, when superimposed on a social structure that is encouraging the emergence of alcohol use, is major. Extensive neuroimaging evidence indicates that alcohol and other substances of abuse have acute and lasting effects on these frontolimbic and frontostriatal systems that are implicated in impulse control and reward responsivity (Moselhy, Georgiou, & Kahn, 2001; Pfefferbaum, Sullivan, Rosenbloom, Mathalon, & Lim, 1998; Tiihonen et al., 1994; Vogel-Sprott, Easdon, Fillmore, Finn, & Justus, 2001; Volkow et al., 1993; Volkow et al., 1988). Such effects are thus being superimposed on

this developing circuitry. Major issues not yet addressed concern the relative importance of amount and timing of alcohol (and other drug exposure) in bringing about such changes, the degree to which other environmental exposures (e.g., stress) also play a role, and the degree to which early neurocognitive vulnerabilities interact with the drug exposure in producing change. An understanding of these processes will require the kind of multilevel-multisystem explanatory structure advanced here. A full explanation will benefit from careful neurobehavioral/neurocognitive characterization that takes into account key aspects of executive functioning and motivation and selected associated systems such as social information processing, along with a characterization of the social context in which they occur. At the same time, it is important to understand how these constructs are actually operating neurally by mapping changes in neural response patterns associated with both risk for alcohol problems and with actual use and its sequelae.

OTHER EPIGENETIC ISSUES

Epigenetic process is by definition interactive, but the degree to which this takes place as a multilevel, multi-system process has received relatively little attention in the literature. In this section, I consider two major factors that contribute to stability and change in risk and disorder over time.

The Nestedness of Environmental, Behavioral, and Neurobiological Risk

From an etiologic perspective, there is special interest in the degree to which risk aggregation is correlated, both at the individual and familial levels as well as at the neighborhood level. At the individual level, the literature has increasingly acknowledged the clustering of comorbid symptomatology, social dysfunction, and psychiatric severity among adults in both AUD (Kessler et al., 1997) and non-AUD populations (Babor, 1996). In fact, as noted earlier, such assortment has been one of the driving forces for the notion that subtypes of disorder need to be demarcated. The association of severe alcoholism with poverty also has a long and visible history (Brenner, 1973; Fitzgerald & Zucker, 1995), and analyses even at the microenvironmental level have documented a clear association between neighborhood disadvantage and alcoholism rates (Pallas, 1992). The most common explanation of this has been that poverty, and the neighborhood structure in which it is embedded, drive the alcoholism (i.e., a top-down explanation). Less clear is the degree to which niche seeking is also

at work here, which would lead persons to seek out and assort in environments as well as in marriages (cf. Scarr & McCartney, 1983). Some evidence suggests that such a process is operative, at least for those with antisocial alcoholism. Thus, antisocial alcoholic men are more likely to marry/couple with antisocial and heavy-drinking/alcoholic women (Zucker, Ellis, Bingham, et al., 1996), and the families they create are more likely to be disadvantaged in their capacity to socialize offspring. Antisocial alcoholism is similarly associated with downward social mobility (Zucker, Ellis, Fitzgerald, et al., 1996), and offspring in these families, even early in life, appear to be developmentally more disadvantaged. They have more learning disabilities and intellectual deficits and show weaker delay of gratification than do offspring from alcoholic but not antisocial families (Nigg, Glass, et al., 2004; Poon, Ellis, Zucker, & Fitzgerald, 1998).

A risk cumulation model would predict that as these factors cumulate, they increasingly create a risk structure that moves the child into peer networks high in aggression, negative mood, and substance use, thus providing a familial, a neighborhood, and a peer structure, all of which act in concert in encouraging the development of (1) an expectancy structure that is positive toward use and abuse of alcohol and other drugs, (2) very early onset for such use, and (3) a stable repertoire of behaviors that are prototypic for the eventual emergence of abuse/dependence. Such environments are also likely to be high in stress, which would impact hypothalamic-pituitary-adrenal axis activity and the development of negative affectivity. Some portions of this emerging matrix have already been confirmed. That is, children from antisocial alcoholic families have earlier onset of alcohol use, and they move more quickly into alcohol problems. Further, their own conduct problems (i.e., their burgeoning antisociality) is a partial mediator of this relationship, above and beyond the effects of the parental alcoholism (Nigg, Glass, et al., 2004).

My colleagues and I have elsewhere described this risk aggregation in certain ecological and familial microenvironments as a “nesting structure” (Zucker, Fitzgerald, et al., 1995) that makes stability of psychopathological outcome much more likely and therefore encourages stability of risk over time. The trajectories of externalizing and internalizing behavior for high-risk youth shown in Figure 17.3 are consistent with this view, although, as noted earlier, the main effects of genetic variation have not been parsed out of that work. Also consistent with this view is the work of Loukas et al. (2003). Although the normal developmental course of child aggressiveness is one of decreasing aggression over the interval from early childhood

to late middle school, Loukas and colleagues found that initial level of child conduct problems as well as level of family conflict separately predicted dampening in the rate of decrease of the aggressiveness. That is, both operated to flatten the decrease in aggressiveness. These data are suggestive of an epigenetic process (Gottlieb, 1991) whereby the organism is shaped not only by “initial value” levels of temperament, by its interaction with a responding environment over time. The individual response changes the environmental response in return, and so on, in an iterative process that leads to developmental change.

I have elsewhere argued that the high-risk aggregation structure changes the process model of risk because the variable network determining the effective causal structure has become sufficiently different; it initially contains more variance pertaining to parental and child psychopathology, social deviance, and neurobiological vulnerability than is true of other nonaggregated structures, and the nested nature of these different risks is therefore more likely to produce coalescence and overlearning of the risky behavioral repertoire than would be true in a less densely risk-laden system (Zucker, Chermack, & Curran, 2000). In contrast, when the microenvironment has less collinearity, the developmental course should be more fluid, and also apparently more probabilistic. This line of reasoning is consistent with normative studies of adolescence that have shown the enhanced effects on drug use and timing of onset when family conflict, association with deviant peers, and poor academic performance are clustered (Duncan, Duncan, Biglan, & Ary, 1998). This is a major issue to understand, and design for, when prevention programming is being developed. Its relevance has been relatively ignored by the prevention community (although see Biglan et al., 2004).

Stability and Change in Alcohol Use Disorder Over Time: Factors Predicting Recovery, or Not

One of the diagnostic categories in *DSM-IV* is remission (early versus sustained, full versus partial). Despite the implicit acknowledgment of course variation that this category provides, the literature has paid surprisingly little attention to the understanding of changes in diagnostic status and adaptation over the adult life course and the critical related questions of what creates stability and change.⁶ The empirical evidence from both epidemiologic and treatment studies is clear that course is not uniform for all alco-

⁶I am indebted to Mary J. McAweeney for her help in writing this section.

holics, whether in treatment or not. A review summarizing results from eight long-term follow-up studies of primarily treatment-recruited alcoholics published between 1982 and 1994 (Vaillant, 1995) noted that approximately 2% per year become abstinent, and that after age 40, approximately 2% die every year.

However, general population studies of alcoholic course suggest a more fluid process. Thus, Hasin, Grant, and Endicott's (1990) general population follow-up study of stability and change in indicators of *DSM-III-R* alcohol abuse and dependence among males over a 4-year interval found that changes away from dependence status involved 54% of the sample (i.e., about half remitted), with 73% of this group remitting entirely. (The parallel figures for the move away from *abuse* involved 46% moving into remission.) Conversely, 46% of those dependent at baseline remained so. Of the initial abuse group, 30% moved into dependence. These rates are quite close to those reported in two more recent and longer-term community prospective studies. Humphreys, Moos, and Cohen (1997), in a study of 395 (50% male) untreated alcoholics followed over 8 years, observed half of the sample to be free of alcohol-related problems at follow-up. Similarly, McAweeney, Zucker, Fitzgerald, Puttler, and Wong (2005) followed 134 community-recruited, initially coupled men meeting criteria for *DSM-IV* AUD diagnosis at baseline. Assessments at three later points over the 9-year interval allowed characterization of intervening course and functioning. They found 44% remitting at the 9-year end point, with approximately half moving out of diagnosis and staying out in during the first 3 years and the remainder experiencing remission at some later point in the interval. Forty-one percent of those meeting diagnosis at baseline continued to make AUD diagnosis over the following 3-, 6- and 9-year intervals, and a small subset of the original group (15%) fluctuated between meeting diagnosis and not meeting diagnosis over the 9 years, but recurring at the 9-year point. Another recent study involving initially untreated alcoholics who were recruited during their first contact with a treatment system observed similar rates of remission, with variation dependent on the level of risk at treatment entry (Moos & Moos, 2003). Subjects with over nine risk factors had a remission rate of 22% and those with two or fewer risk factors had a remission rate of 76% after 8 years.

The risk factors identified by the Mooses and others as contributing to better or worse outcome are of several types. Moos and Moos (2003) found that more participation in Alcoholics Anonymous (AA) or formal treatment over the 8-year follow-up period predicted remission. Also, alcoholics who at baseline consumed more alcohol were in-

toxicated more often, had a heavier drinking pattern, and had increased tolerance, were more likely to be nonremitted at 8-year follow-up. In contrast, in the Humphreys et al. (1997) nontreatment sample, addictive behavior factors such as alcohol consumption and alcohol dependence at baseline did not predict recovery. This was also true in the McAweeney et al. (2005) nontreatment sample. More generally, the existing literature indicates that recovery (movement out of diagnosis, and then staying out) is a dynamic behavior change process at the individual level, involving continued practice of lifestyle change, which reinforces and perpetuates a desire to maintain the change in a positive spiral (Kaskutas, Bond, & Humphreys, 2002; Prochaska, DiClemente, & Norcross, 1992; Vaillant, 1995). For instance, it has been shown in both natural and treatment settings that a pattern of decreased drinking or total abstinence from drinking produced a rise in self-esteem, lessening of depression, and greater confidence to resist drinking (Blomqvist, 1999; S. M. Hall, Wasserman, & Havassy, 1991; Humphreys, Moos, & Finney, 1994).

The across-study discrepancy in the utility of baseline symptom severity as a predictor of later outcome highlights another issue. The McAweeney et al. (2005) study found that social environmental factors played a role in recovery that overrode the effects of current alcoholic functioning. Thus, the study found that wives' baseline AUD status and the extensiveness of their social support network were robust predictors of recovery from diagnosis, above and beyond the alcoholic husband predictors of higher educational achievement, treatment involvement, and the help of a history of prior success (more intervening years of recovery). A parallel set of findings was observed in the Humphreys et al. (1997) study, where social/community resources were more predictive of recovery than individual demographic variables. The effective social/community resources included being an active member of a religious organization, number of outpatient treatment sessions, family relationships, and attendance at AA meetings. One possible reason for the across-study difference in predictive utility of drinking severity at baseline may lie with the difference in populations being studied. In community samples, greater levels of variation exist in social relationships. When the social environment is less fluid, more likely in treatment samples that tend to be older and involve more socially damaged alcoholics, then the severity indicator at baseline may be a more effective predictor.

Thus, recovery from diagnosis appears at least in part to be an interactive, epigenetic process that may not be entirely predictable on the basis of prior history. More than a

generation ago, Moos, Finney, and Chan (1982) observed that spouses of relapsed alcoholics drank more alcohol and participated in fewer social activities. These findings suggest that the marital partner's ongoing functioning plays a role in stability or change of their husband's diagnosis. A parallel observation in the McAweeney et al. study suggests the same. Recovered men's partners decreased their AUD in the interim, but nonremitters' partners increased. The next step for research in this area clearly needs to move to the microanalytic, real-time level of social interaction to isolate the critical behavioral and interactional ingredients that create these macrolevel variables. Such factors might include the quality of microinteractions between partners (leading to divorce or not), the level of negativity associated with the drinking, the specific nature of peer relationships, and their social networks outside the marriage (Jacob, Leonard, & Haber, 2001; Leonard & Jacob, 1997; McCrady, Hayaki, Epstein, & Hirsch, 2002). At the same time, it is conceivable that the putative interactive effects are a product of marital assortment, which thereafter is responsible for the differences in marital interaction and social functioning of partners. This hypothesis will also need to be evaluated, although evidence to date is not consistent with this explanation (Floyd et al., in press).

FUTURE WORK AND CONCLUDING SUMMARY

In this section, I comment on three next-step problems that the field needs to address. They involve the need for (1) redefinitions of the phenotype, (2) a change in the core paradigm of the field, and (3) better articulation of gene-brain-behavior-environment relationships.

Redefining the Phenotype

A number of generalizations about the characteristics of AUD are derivative from this review:

- The etiology of AUD is emergent, and significant portions of the risk structure are identifiable in very early childhood.
- Variations in trajectory of risk in earlier life and symptomatology and course in adulthood provide clear evidence that AUD is a heterogeneous family of disorders, and the time has passed for it to any longer be regarded as a single phenotype. In its crudest form, the AUD category is differentiable into an early-onset, high-risk, high-chronicity trajectory that emerges out of a nested matrix involving high individual undercontrol and high family, socioenvironmental, and genetic risk, and a number of shorter course trajectories that appear to be strongly driven by environmental, stage-dependent (late youth and young adulthood) influences or specific environmental stressors (divorce, death, trauma/abuse). A third group display as gradual-onset, primary addictions to ethanol that occur in high-use environments among those with a prior drug vulnerability (e.g., low sensitivity to ethanol) and that continue without significant co-occurring psychiatric comorbidity.
- The occurrence of externalizing or internalizing symptomatology, or both, or neither, in childhood and externalizing or internalizing disorder, or neither, in adulthood is critical to the classification of the phenotype.
- Because risk is emergent and takes place in a fairly well-defined risk matrix, cross-sectional classification of symptomatology in adulthood is not a sufficient marker of course. A new diagnostic framework is required that takes account of trajectory variation, onset characteristics (early versus later; within a high-adversity, nested risk environment or not), and offset characteristics (how long symptomatology has been absent; whether it has recurred or not, and if it has, its duration and severity) and that evaluates the degree of risk of the nesting structure within which the current symptomatology is embedded.

The author and colleagues began such a formulation in the early 1990s by creating an index to scale the "mass" and "momentum" of the disorder (Zucker, 1991; Zucker, Davies, Kincaid, Fitzgerald, & Reider, 1997). The index, called the Lifetime Alcohol Problem Score (LAPS), is a developmentally based measure that conceptualized the disorder as a mass of greater or lesser breadth (indexed by variety of different symptoms) with properties of extensiveness in time and life course invasiveness (the index had an onset component, a "life-% with symptomatology" component, and a more recent version also has an offset component; Jester et al., 2001). It has proven to be an effective dimensional measure of life course diagnostic weight in a number of different studies (e.g., McAweeney et al., 2005; Wong et al., 1999), but it has not been widely used outside of our own group.

- Ethanol has been called a "dirty" drug, because there are so many sites of action in the brain that appear to have relevance in the development and maintenance of the addictive disorder. In parallel, this review clearly in-

icates that the etiology of this family of disorders is likewise dirty, involving a large matrix of causal systems that operate in concert to produce one or another of the AUD end points. Apropos point two, the different concerts need to be better differentiated and scored for the field to move to the next level of understanding of the family.

Is the Child Father to the Man, or Mother to the Woman? Problems in Embracing a Developmental Psychopathology Paradigm

As noted in point 1, and as articulated at some length earlier in this chapter, eight different longitudinal studies conducted in three countries have replicated the finding that early externalizing and internalizing problems are developmental precursors of AUD. The earliest of these studies was published almost a generation ago. Thus, it remains extraordinarily puzzling that this work has not been integrated into the common knowledge base and remains virtually unknown by the treatment community. Conversely, in the past several years, considerable attention has been given to a developmentally intermediary indicator of course and of AUD risk, namely, early onset of drinking. There are a host of studies that have observed this relationship in the past decade, and National Longitudinal Alcohol Epidemiologic Survey (NLAES) data have also documented it (Grant, 1998; Grant & Dawson, 1998). But from the perspective of a developmentalist, that marker, and those processes, are already well down the road of risk development.

There are a number of reasons this problem still exists. I have recently addressed some of the clinical and social policy reasons for this state of affairs (Zucker & Wong, 2005). But for this set of volumes, it is more appropriate to note that an epigenetic understanding of risk and disorder still remains outside the accepted framework of understanding for substance use disorders more broadly. I hope this chapter will contribute to rectifying this situation. It remains a major issue for the field to address.

(As a historical note, when this chapter was written in the summer and fall of 2004, this was the situation. But during that time, under the direction of NIAAA Director Ting-Kai Li, a major shift in the Institute's direction began, which reconceptualized alcoholism as a developmental disorder whose origins begin before adulthood. A number of new initiatives were started, foremost among which was NIAAA's Underage Drinking Initiative [<http://www.niaaa.nih.gov/about/underage.htm#welcome>], which, with the help of an outside team of experts, has

begun to explore the precursive elements in this process at levels ranging from the genetic to the systemic, and ranging back in developmental time from conception into early childhood, and thereafter. The initiative not only represents a major reframing of the core nature of the disorder, including nonspecific-to-alcohol as well as alcohol-specific components, but it also articulates a perspective on behavior disorder that represents a paradigm shift for a national policymaking body charged with understanding the causes, etiology, and treatment of a major psychopathological disorder. It is noteworthy that the two main professional organizations whose membership deal with these issues on a day-to-day basis, the American Psychiatric Association and the American Psychological Association, have not yet made that shift.)

Articulating Specific Gene-Brain-Behavior-Environment Relationships

Given current developments in molecular biology and statistical genetics, earlier questions about heritability and relative effects of genes and environment are no longer important for the field to consider. Alcoholism, in its varying forms, is both a genetic and an environmental disorder (A. Heath, 1995; Jacob et al., 2001; McGue, 1994), and next-step research needs to be focused on questions of mechanism: of which genes, acting in which combinations, affect which intermediary neurobiological systems in the development of risky traits, which, if emergent long enough, under exposure in critical risky environments, will lead to the clinical phenotypes of alcoholic disorder.

In this multilevel explanatory structure, it is equally important to understand the role of specific environmental influences in stimulating or dampening gene expression and, in parallel fashion, stimulating or dampening behavioral expression of the risky trait(s), and in allowing it (them) to remain in place long enough to become specialized. Time is also a significant part of this multifactorial structure, functioning as a proxy for development. A mounting body of evidence has demonstrated that these processes are dynamic, involving the creation of a chain of risk that varies developmentally and whose course appears not to be the same for individuals with different clusters of risk (Kuh et al., 1997; Zucker, 2000). Solving this puzzle requires a multidisciplinary team with expertise ranging from molecular genetics to life span developmental psychopathology. It also is an analytically very demanding puzzle, given the multilevel, multigene, across-time nature of the required models. At the same time, with the appropriate database, modeling of

these interrelated domains would provide the first integrative descriptions of the development of the disorder.

Summary and Concluding Remarks

A multilevel-multidomain set of factors produces life course variation in alcohol use, abuse, and dependence. At the macro level, the rule, availability, and activity structure of the larger society plays a significant role in regulating drinking behavior. This larger social system restrains heavy consumption in some eras and in some community settings, and allows it to flourish in others, and level of dampening even has impact on population rates of AUD. Prohibition and wartime rationing are but two extremes of a phenomenon that continues to change as lawmakers and policymakers dampen down or open up the availability and penalty structure for use. In turn, social environmental availability makes alcohol-seeking behavior easier or more difficult, and the cuing it provides encourages use to the degree that it activates existing individual expectancy and motivational networks.

Thus, to a degree, alcohol-seeking and -using behavior is social behavior because it occurs in response to the social environment. However, it is considerably more than that. The use of ethanol is a self-dosing act, and the pharmacodynamics of the drug experience engage the brain's structures for appetite, sensitization, adaptation, reward, planning and forethought, and affective and behavioral control. This activity, and the network of risk factors connected to it, is characterizable at a number of levels of specificity, ranging from the behavioral to the neuroanatomical to the genetic.

Behavioral risk involves an expectancy network about the positive or negative effects of alcohol use, that has its beginnings in early childhood, and develops over time as a function of both observational learning and consumption. Two major traits nonspecific to alcohol use, undercontrol and negative affectivity, also are major predictors of early use, of problem use and ultimately of AUD. They also are predictive that adult disorder will be more severe and more socially problematic.

Brain circuitry related to these behaviors includes circuitry regulating stress and anxiety, response suppression, working memory, reward responsivity, and social information processing and involves both cortical and subcortical sites.

The heritable basis of behavioral risk has been firmly established over the past generation and accounts for 40% to 60% of the risk variance. Heritability of AUD is heavily non-drug-specific, and the risk pathway is primarily

through the two intermediate behavioral phenotypes of undercontrol and negative affectivity. At the same time, several genes conveying specific risk for AUD on the one hand, and protection on the other, have also been identified. Promising candidate genes regulate aspects of the serotonin, dopamine, and GABAergic systems. More generally, the genetics of AUD is that of a complex trait, involving heterogeneity of phenotype, multiple genes, a significant environmental set of risks, and developmental variation in course.

This matrix is a multidisciplinary puzzle, and the problem from a science and a training standpoint is that most investigations are still single discipline activities, with each investigative group attempting to capture the explanatory variance from the vantage point of their own discipline. The current state of knowledge is at a point that such efforts are increasingly of limited value because the models they generate underspecify the risk matrix and are unable to evaluate the critical interactions that the current data suggest are in operation.

For the same reason, the resolution of this puzzle requires an interdisciplinary effort to resolve, and anything less is going to fall short. The same concern needs to be voiced about policy formulations that focus on only one level of the dilemma while ignoring the others. A sufficient knowledge base now exists to begin to address this family of problems at multiple levels of cause and at multiple places in their life history.

CHAPTER 18

Dissociative Disorders

FRANK W. PUTNAM

WHY IS DISSOCIATION INTERESTING FROM A DEVELOPMENTAL PERSPECTIVE?	657
GOALS OF THE CHAPTER	658
BRIEF HISTORY OF DISSOCIATION AND THE DISSOCIATIVE DISORDERS	659
Eighteenth and Nineteenth Century	659
Twentieth Century	660
Modern Perspectives on Dissociation	660
DEFINITIONS OF DISSOCIATION	661
Dissociative Symptoms	661
CLINICAL AND RESEARCH MEASURES OF DISSOCIATION	664
Dissociation Scales and Diagnostic Interviews	664
Symptom Screening Measures	664
Diagnostic Interviews	665

WHY IS DISSOCIATION INTERESTING FROM A DEVELOPMENTAL PERSPECTIVE?

The concept of dissociation as a psychopathological process has long been controversial. For well over a century this controversy has raged, and it remains as acrimonious now as it has ever been (McHugh & Putnam, 1995). Yet, an increasing number of clinicians and researchers, especially those with a developmental orientation, are including measures of dissociation in their clinical practice and research studies. Dissociation is now considered by some researchers to be a major mediating factor for the development of certain types of psychopathology. The growing recognition of the impact of dissociation on long-term psychological health emerges both from clinical work with traumatized individuals and from research with normal

and clinical populations. Dissociation appears to account for a significant amount of the variance in specific psychopathological outcomes as well as for some important clinical phenomena.

In parallel with the growing recognition of the contribution of dissociation to psychopathology is an emerging awareness of dissociation as a fundamental developmental process, similar to emotional regulation, in that it more or less continuously shapes a child's interaction with his or her environment during sensitive periods. As a result, high levels of dissociation appear to profoundly influence the long-term development of identity and sense of self, cognitive functioning, and psychological and physiological responses to stressors in some individuals (Putnam, 1997).

Indeed, if the taxonic model of Dissociative Identity Disorder (DID) is correct, then high levels of dissociation

acting over the course of early development produce a distinctly different type of psychological organization. In opposition to a unified sense of self, dissociative individuals experience themselves as a collection of independent or semi-independent agents, referred to as “personality systems,” which are often at cross-purposes. Some researchers believe that understanding the effects of early dissociation on child development will provide crucial insights into the effects of early trauma and psychosocial adversity on long-term mental health.

GOALS OF THE CHAPTER

The overall goal of this chapter is to provide a comprehensive developmental, clinical, and research overview of dissociation, its history, phenomenology, the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* taxonomy, developmental precursors, diagnosis, and treatment.

The history of dissociation is instructive in that it exemplifies both the enduring conceptual influence that early theorizing about the nature of a disorder can have on modern formulations and the troublesome baggage that such theorizing leaves in its wake. It has been said that much of what mental health professionals know about the dissociative disorders is based on the portrayal of Multiple Personality Disorder in the popular media. From their earliest clinical accounts in the eighteenth century onward, dissociative disorders have evoked public fascination. Many of the misleading stereotypes about these conditions originated in the popular media over a century ago and have been promulgated forward ever since. A goal of this chapter is to trace the early historical roots of dissociation theory and its subsequent revisions in the light of new and better data.

The history of dissociative disorders is interesting in that it is also, in many respects, the history of the emergence of psychodynamic psychiatry. Dissociative psychopathology, such as double personality, fugue, somnambulism, psychogenic amnesia, and depersonalization, was pivotal in the larger recognition of the existence and influence of unconscious processes on behavior. These dissociative conditions, in which an individual behaved in ways that were often antithetical to his or her normal behavior and interests, spurred the recognition of a hidden mental world that could erupt and take control of an individual's thoughts and actions in times of personal crisis. Most of the great figures of early nineteenth-century psychology and psychiatry described cases

and presented their theories of dissociation. The cumulative result was the “discovery of the unconscious” during the late nineteenth century and the subsequent articulation of therapeutic approaches that directly addressed unconscious processes in treatment (Ellenberger, 1970). Freudian psychoanalysis is the most notable of these treatments, but many other dynamic psychiatry treatment models exist and are still practiced.

Psychoanalysis, once the dominant psychiatric treatment model, has long since lost its cachet and been replaced by neurobiologically oriented approaches to treatment, primarily psychopharmacology. Dissociation, however, remains clinically and scientifically important to current theorizing, especially as related to the development of psychopathology, the nature of cognitive processes, and the linkage between mental processes and somatic symptoms. An awareness of the history of dissociation and the dissociative disorders will help the reader appreciate the critical role of dissociation in understanding mental illness and health as well as to sort the proverbial wheat from the chaff with regard to the claims and counterclaims raised by proponents and opponents of dissociation theory.

Another goal of this chapter is to articulate the essential features of dissociation and the corresponding dissociative diagnoses such that clinicians can recognize these conditions in their work and researchers can include dissociation in their clinical and laboratory investigations. In this regard, the chapter seeks to delineate the nature of dissociation through a convergence of data drawn from multiple sources.

Dissociative disorders have been formally defined in every version of the *DSM* published by the American Psychiatric Association since *DSM-I* in 1952. A number of the *DSM*-defined disorders are discussed in this chapter to provide detailed descriptions of dissociative psychopathology. These discussions include the essential features of the disorder, a table of the *DSM-IV-TR* diagnostic criteria, relevant epidemiology, and a brief description of currently accepted treatment. In addition to the *DSM* disorders, the chapter includes more general discussions of dissociative symptoms that commonly occur across most of the *DSM* disorders and thus can be considered core symptoms.

The best validated approaches to the measurement of dissociation are also discussed. Current dissociation scales and structured interviews for adults have been proven to be as reliable and valid as corresponding measures for depression and anxiety. Although fewer in number, dissociation measures for children and adolescents also exhibit good

psychometric properties and are proving informative both clinically and in the laboratory setting. The inclusion of standard dissociation measures in clinical and experimental research has revolutionized our understanding of the dissociative process. A goal of this chapter is to review existing quantitative research using standard dissociation measures on etiological antecedents, the impact of dissociation on development, dissociative alterations of cognition, and the neurobiological markers and mechanisms of dissociation.

One of the major results of this process is the documentation of the role of trauma in the etiology of pathological levels of dissociation. Historically, dissociation has been linked to trauma since the nineteenth century by authorities such as Pierre Janet (van der Kolk, Brown, & van der Hart, 1989; van der Hart, Brown, & van der Kolk, 1989) the great French psychologist and psychiatrist. The advent of good measures of dissociation allows us to quantify this early observation for multiple different types of trauma in independent samples. The magnitude of the relationship of increased dissociation to traumatic antecedents is equivalent to that demonstrated for trauma and posttraumatic stress symptoms. Induced stressor studies, such as those conducted on military training of Special Forces troops, further strengthen our conviction that experiences of major stress and trauma play an etiological role in the production of pathological levels of dissociation.

A second process making an etiological contribution to dissociation appears to be a particular disorder of attachment, Type D or Disoriented/Disorganized Attachment. Type D attachment, most commonly found in maltreated children, appears to be an important antecedent process that predisposes individuals to dissociate in the context of stress or trauma as opposed to exhibiting some other symptomatic expression and/or coping response. Preliminary longitudinal data linking Type D attachment in infancy to subsequent increased dissociation in adolescence suggests that, together with early maltreatment/childhood stressors, fundamental parent-child difficulties contribute to the propensity to dissociate.

A final important goal of this chapter, in keeping with the theme of this book, is to describe the current data and thinking with respect to dissociation as a critical developmental process influencing cognition, behavior, and psychopathology. A growing body of research is strongly linking dissociation to a range of negative long-term sequelae. Sophisticated statistical studies confirm that dissociation plays a significant role in the mediation of traumatic experiences into these negative outcomes. An awareness of the powerful developmental role played by

increased dissociation in certain forms of psychopathology provides a clinical target for the next generation of treatments and interventions with maltreated and traumatized children.

BRIEF HISTORY OF DISSOCIATION AND THE DISSOCIATIVE DISORDERS

Eighteenth and Nineteenth Century

The study of dissociation began in the late eighteenth century with Eberhardt Gmelin's (Ellenberger, 1970) medical report of a German woman who alternatively "exchanged" her peasant personality for that of a French aristocratic lady, with each personality amnesic for the other. By the early nineteenth century, diagnoses of dual, double, and duplex personality/consciousness were being regularly reported in Europe and North America. Widely hailed as the father of American psychiatry, Benjamin Rush (Putnam, 1991) included examples in his medical school lectures. He proposed that the condition was caused by a disconnection between the two hemispheres of the brain—a theory that continues to attract modern interest. The case of Mary Reynolds, which was to become the American archetype of multiple personality for the remainder of the century, was first described shortly thereafter.

In France, Antoine Despine (Despine, 1840) a country doctor, compiled systematic case reports of several multiple personality patients, including child and adolescent cases. Many also suffered from classic conversion symptoms such as psychogenic blindness, deafness, and paralysis. It was then commonly believed that these patients, primarily women, suffered from sexual frustration. Hysteria became the preferred diagnosis for these patients. In a mid-nineteenth-century study involving nuns, prostitutes and maid servants, Paul Briquet (Ellenberger, 1970) disputed the notion that hysteria was an expression of forbidden impulses. He believed instead that these symptoms arose as a result of overwhelming trauma and loss, frequently in childhood.

Toward the end of the nineteenth century, Jean-Martin Charcot (Ellenberger, 1970), director of the great French psychiatric hospital La Salpêtrière, gave dramatic demonstrations with "hysterical" patients who were "magnetized" before crowds of physicians and the interested public. Among those attending were Sigmund Freud, Pierre Janet, and Joseph Babinski. Following Charcot's

sudden death, Babinski (Babinski, 1901, 1909), who believed that the patients' symptoms were merely the effects of Charcot's "suggestion," assumed directorship of the Salpêtrière and halted further studies, thereby roundly discrediting dissociation and hysteria. The then considerable prestige of French psychiatry influenced the adoption of similar positions internationally, although American academic interest in dissociation continued into the early twentieth century under the influence of William James, Morton Prince, and others.

Pierre Janet (Ellenberger, 1970), though similarly critical of Charcot's performances as encouraging of hysterical symptoms, nonetheless recognized the existence of a legitimate underlying mental disturbance. Conducting carefully documented case studies (ultimately numbering in the thousands, which he ordered destroyed upon his death), Janet elucidated the psychological principles that he believed characterized dissociative psychopathology. As had Briquet a half-century before him, Janet attributed hysteria to overwhelming stress and actual trauma. He believed that the fundamental process in dissociation was the "narrowing of consciousness," which prevented the person from perceiving certain subjective phenomena, such as traumatic memories. These then became dissociated, quasi-independent aspects of the mind. He developed a cognitive psychotherapy, including hypnosis, which sought to identify and correct these "fixed ideas." The First World War interrupted Janet's writing and teaching, and in the immediate postwar years the rise of psychoanalysis, with its emphasis on repression of unacceptable ideas and impulses, eclipsed his earlier therapeutic approach of "psychological analysis."

Today, most authorities regard Janet as the father of modern theories of dissociation and note that many of Freud's early ideas were borrowed from him. Indeed, Freud cites Janet's work in his first book, *Studies on Hysteria*, coauthored with Josef Breuer, which is widely revered as the beginning of psychoanalysis (Breuer & Freud, 1957). In his review of their book, Janet somewhat sarcastically observes that these young Austrians have discovered some of his "already old ideas" (Ellenberger, 1970, p. 772). As time passed, however, many psychoanalysts severely criticized Janet, and his ideas were largely repudiated or forgotten in the post-World War I infatuation with Freud's theories about sexual drives. Psychoanalytic thinking posited the idea of a dynamic unconscious, which defended against unacceptable thoughts, wishes, and memories. Freud's subsequent retraction of his seduction theory further detracted from Janet's position that hysterical patients had experienced actual trauma.

Twentieth Century

World War II brought many "hysterical" battlefield casualties, called "shell shock" in WWI, who exhibited florid dissociative reactions, including amnesia for their own identity, fugues, conversion blindness, and paralysis. Treatment generally involved "narcosynthesis," induced by hypnosis or drugs such as sodium amytal, which created a twilight mental state in which the traumatic memories underlying the symptoms were recalled and defused in an often emotional abreaction. Although their long-term effects were never followed up, these battlefield treatments were regarded as hugely successful, returning the vast majority of soldiers to the front lines within days (Menninger, 1945). Despite initial optimism, the successes of military psychiatry with abreactive treatments for acute traumatic reactions could not be duplicated with peacetime mental patients. The majority of these patients suffered from chronic forms of mental illness such as Schizophrenia and Bipolar Disorder. As a consequence, abreactive forms of therapy were largely discarded in the 1950s, only to be rediscovered and used with Vietnam veterans and Dissociative Disorder patients in the 1970s and 1980s.

The publication of the *DSM-III* in 1980 brought new attention to the dissociative disorders as a distinct category of psychiatric conditions. This renewed recognition of dissociation, especially Multiple Personality Disorder, stimulated both clinical recognition and reporting and more formal research. Subsequently a large body of data has accrued for DID (as Multiple Personality Disorder was renamed in the *DSM-IV*), Depersonalization Disorder, and dissociation in general.

Modern Perspectives on Dissociation

From the 1980s on, clinicians and researchers have reported high rates of trauma, particularly child abuse, in Dissociative Disorder patient samples. These reports, together with sensationalized media portrayals, have contributed to a series of controversies that have affected the credibility of dissociation despite the overwhelming scientific data attesting to its validity as a pathological process. The core controversies are (1) whether Dissociative Disorders, particularly DID, are an iatrogenic creation induced by the therapist's fascination/credulity with a "suggestible" patient and (2) whether the traumatic memories recalled by many of these patients are based on actual experiences (McHugh & Putnam, 1995). These primary controversies, which are both predicated on a notion of increased "suggestibility," have become politicized around

the implicit issue of true versus false claims of victimization. These controversies have overshadowed much of the research findings published in the past decade. Indeed, the two sides generally discount each other's data, although relevant research has been done by both camps.

DEFINITIONS OF DISSOCIATION

Definitions of dissociation emerge from a number of disciplines and research traditions, including hypnosis research, descriptive psychiatry, information-processing theory, and cognitive psychology. These definitions converge around the notion that dissociation is manifest by the failure to connect or associate mental information in the fashion that it would normally be expected to be linked. The *DSM-IV* states that "the essential feature of the dissociative disorders is a disruption in the usually integrative functions of consciousness, memory, identity, or perception of the environment. The disturbance may be sudden or gradual, transient or chronic" (American Psychiatric Association, 1994, p. 477).

This failure to integrate certain kinds of information operating over the course of development gives rise to a set of life experiences that shape both dissociative and compensatory behaviors. As a result, most measures of dissociation ask about the frequency with which certain "unusual" experiences occur. For example, the Dissociative Experiences Scale (Bernstein & Putnam, 1986) asks, "Some people have the experience of finding themselves in a place and having no idea how they got there. Circle a number to show what percentage of the time (0% to 100% in 11 steps) this happens to you." This question inquires about fugue episodes, a common experience for many people with DID but extremely rare for individuals who do not qualify as having a Dissociative Disorder.

Dissociative Symptoms

For the most part, clinically based measures of dissociation inquire about the same basic set of constructs: (1) amnesias and "lost" time; (2) alterations in sense of identity; (3) depersonalization and derealization; (4) experiences of intense absorption; and (5) passive influence experiences. Most dissociation measures do not include all of these constructs, leading to some variability across studies. However, there is very high convergent validity across the most widely accepted measures of dissociation. A meta-analysis yielded an overall combined correlation of $r = .67$ with a Cohen's $d = 1.81$ (a Cohen's $d \geq 0.80$ is considered evidence of a strong effect; van Ijzendoorn & Schuengel, 1996).

Each of these dissociative constructs is typically manifest both as a set of subjective experiences that the individual may report and as a set of distinct behaviors that may be observed, recorded, and to some extent quantified. The phenomenology of these dissociative signs and symptoms has shown good stability across culture and over time. Janet's nineteenth-century dissociative patients by and large resemble those seen on psychiatric wards today. Clinical dissociative case series have been reported for many different cultures, including non-Western, Latin, Asian, European, and Near Eastern (Boon & Draijer, 1993; Coons, Bowman, Kluft, & Milstein, 1991; Middleton & Butler, 1998; Sar, Yargic, & Tutkun, 1996). Comparisons of symptoms reveal many strong similarities across these different samples. This reliability in the clinical manifestations of dissociation across time and culture is one element of a larger proof of the validity of pathological dissociation as a meaningful construct and the dissociative disorders as a distinct manifestation of psychopathology. Nonetheless, it should be acknowledged that there are cultural variations in clinical dissociative presentations, so that different cultures may package the core set of dissociative constructs in unique ways.

The five *DSM* dissociative disorders, Dissociative Amnesia, Dissociative Fugue, Depersonalization Disorder, DID, and Dissociative Disorder Not Otherwise Specified (DDNOS), share overlapping dissociative symptoms. Each disorder is characterized by a primary dissociative symptom that dominates the clinical presentation, but careful inquiry will reveal the existence of other dissociative symptoms. To further confuse the reader, many dissociative symptoms share the name of the *DSM* disorder. For example, Dissociative Amnesia is both a symptom that may be found in several dissociative disorders and the name of a *DSM* disorder. To clarify for the reader whether a symptom or a *DSM* disorder is being discussed, all *DSM* disorders are capitalized in the text.

Amnesia and Memory Symptoms

Time loss, blackouts, and various amnesias in the absence of substance abuse or organic conditions are a hallmark of pathological dissociation. Specific disturbances in memory are core features of all of the dissociative disorders except perhaps Depersonalization Disorder. Patients generally report becoming aware of these gaps in the continuity of their memory in two ways. In the first instance, they "come to" in the midst of doing something, for example, finding themselves in a room talking with strangers or driving in a car. Often, they have little or no recall of how they got to be where they are or what they were doing there. The second

way that large gaps in awareness of the continuity of time come to an individual's attention is when that person is continually confronted with evidence of having gone somewhere or done something that he or she cannot recall. Family and friends tell these individuals about events and behaviors that they cannot remember, they find purchases that they do not recall buying, or they find themselves married to people whom they do not know. One patient told me that she was tired of going to work and discovering that she had quit her job in a stormy scene the day before.

Family and friends often describe the patient as forgetful or as always changing his or her mind. There is a perplexing quality to this forgetfulness in that the individual often appears not to recognize people or possessions or forgets important information that he or she would be expected to remember without difficulty. At other times, a dissociative individual may show profound shifts in personal preferences, for example, taste in food or clothing, and refuse to acknowledge his or her prior favorite choice. Dissociative individuals often report significant gaps in the continuity of their autobiographical memory. For example, a patient reported that she had clear memories of fifth and sixth grade but no recall of seventh and eighth grade. These gaps in autobiographical recall do not fit the profile of "childhood amnesia," which typically manifests as a significantly decreased number of memories below age 5 to 6 years, with few memories before age 3 years. Rather, dissociative patients often report abrupt, age- or event-demarcated gaps in autobiographical recall that do not fit the memory decay curve associated with childhood amnesia.

Dissociative disturbances of memory wax and wane dynamically so that information that was unavailable in one context may be readily available in others. Generally the individual and his or her significant others find ways to rationalize these discrepancies in memory, preferences, skills, and knowledge until some event occurs that makes it overwhelmingly evident that this level of forgetfulness is seriously compromising the quality and effectiveness of the individual's performance. Nonetheless, high levels of dissociation operating over the course of development shape an individual's approach to situations and his or her responses to certain events.

Alterations in Identity

Alterations in identity are a critical feature of all dissociative disorders and a core component of pathological dissociation. These alterations take a number of forms. In Dissociative Amnesia, the individual loses awareness of his or her identity; these are the John and Jane Doe cases who show up in most large city hospital emergency rooms sev-

eral times a year. In Dissociative Fugue, characterized by a sudden trip or wandering episode, the individual is largely amnesic for his or her principal identity but often elaborates a secondary identity during the journey. When the primary identity is reestablished, there is often a reciprocal amnesia for the events and experiences of the secondary identity. Memory for fugue experiences may, however, return gradually or in response to specific cues. In Depersonalization Disorder, the individual often feels either "unreal" or "dead." Dissociative Identity Disorder or Multiple Personality Disorder is characterized by individuals feeling as if they consist of a number of separate and distinct alter identities or personalities that exchange control over behavior, often in a rather contentious fashion. The *DSM* category of DDNOS is a heterogeneous collection of dissociative syndromes and trance state conditions, many unique to specific cultures or situations, which typically includes full or partial spirit possession experiences or episodes during which the individual is not fully cognizant of his or her identity and behavior.

Depersonalization and Derealization

Depersonalization is both a symptom and a *DSM* disorder. As a psychiatric symptom, depersonalization is remarkably common and is included among the symptom profiles of a wide span of disorders, ranging from epilepsy to Borderline Personality Disorder. The *DSM-IV-TR* identifies the essential feature of depersonalization as the persistent or recurrent feeling of detachment or estrangement from one's self. The individual may report feeling like an automaton or as if in a dream or watching himself or herself in a movie. There may be a sensation of being an outside observer of one's mental processes, one's body, or parts of one's body. There is often a sense of an absence of control over one's actions.

Described clinically since the 1870s, depersonalization was named in 1898 by L. Dugas (Dugas, 1898), who sought to convey "the feeling of loss of ego." Freud, Janet, Eugén Bleuler, and other nineteenth-century authorities reported patients with symptoms of depersonalization and derealization. A 1914 report by Schilder (1939) is regarded as a turning point in psychiatric interest. In 1954, Ackner (Ackner, 1954a, 1954b) enumerated the essential features of current diagnostic definitions. Symptoms of Depersonalization as a *DSM* disorder include

- (1) the feeling of unreality or strangeness apropos the self;
- (2) the retention of insight and lack of "delusional elaboration";
- (3) the lack of affective response ("numbness") except for the discomfort regarding depersonalization; and
- (4) an unpleasant property that inversely varies in intensity

with the subject's familiarity with the phenomenon. (Kaplan & Sadock, 1991, p. 51)

In the past decade, research by Eric Hollander, Daphne Simeon, and colleagues (Hollander et al., 1990, 1992, 1994; Simeon et al., 1997, 2000; Simeon, Guralnik, Knutelska, Yehuda, & Schmeidler, 2003; Simeon & Hollander, 1993) has significantly increased our understanding of Depersonalization Disorder through systematic case series, medication trials, brain imaging, and improved measurement.

Derealization is defined as a "sensation of changed reality or that one's surroundings have altered" (Kaplan & Sadock, 1991, p. 51). Derealization is quantified on dissociation scales by questions such as "Have you ever felt as if the world and/or people around you was unreal, or seemed as if in a dream (Bernstein & Putnam, 1986)?"

Transient experiences of depersonalization and derealization are the third most commonly reported psychiatric symptom after depression and anxiety. A random sampling of over 1,000 adults found a 1-year prevalence of 19% for depersonalization and 14% for derealization (Aderibigbe, Bloch, & Walker, 2001). Common in seizure patients and migraine sufferers, depersonalization also occurs with the use of marijuana, LSD, and mescaline, and less frequently as a side effect of certain medications, particularly anticholinergic agents. Albert Hoffman, the chemist who first synthesized LSD, reported on his first deliberate ingestion: "Occasionally I felt as if I were out of my body. . . . I thought I had died. My 'ego' was suspended somewhere in space and I saw my body lying dead on the sofa" (quoted in Lee & Shlain, 1992, p. xviii). Depersonalization has also been reported following meditation, hypnosis, mirror and crystal gazing, and sensory deprivation experiences. It is also common after mild to moderate head injury where there is little or no loss of consciousness; for some reason, it is much less likely if unconsciousness lasts for more than a half-hour. Depersonalization, derealization, or out-of-body experiences are also common following life-threatening experiences with or without serious bodily injury and may occur in up to 70% of individuals with a serious injury or near-death experience (Putnam, 1985).

Experiences of Intense Absorption and Deep Hypnosis

Experiences of intense absorption, deep hypnosis, or deep relaxation are considered dissociative by some, but by no means all, authorities. Their inclusion as dissociative comes out of the hypnosis research tradition, which has long equated hypnosis with dissociation. A number of lines of evidence, however, indicate that clinical phenomena that are often referred to as "pathological dissociation" are distinct

from seemingly analogous phenomena that may be induced under hypnosis in highly hypnotizable individuals. More than a dozen studies that have administered measures of both hypnotizability and dissociation found virtually no correlation between these two constructs (Putnam & Carlson, 1998). Nor do measures of hypnotizability correlate with psychopathology in the same fashion as dissociation. As a consequence, many authorities are dropping absorption items from their scales and interviews, as these are not predictive of clinical consequences.

Passive Influence/Interference Symptoms

Passive influence or interference symptoms encompass many first-rank Schneiderian symptoms, such as audible thoughts, voices arguing with each other, divine or demonic powers controlling the body, thought withdrawal or insertion, and "made" feelings, impulses, and actions. Once considered to be pathognomonic for Schizophrenia, passive influence experiences are not uncommon in patients with affective, organic, and dissociative disorders. In fact, passive influence symptoms are more common in dissociative patients than in patients with psychotic disorders (Kluft, 1987). In dissociative patients, the agents of the passive influence symptoms are usually experienced as internal, as opposed to individuals with psychotic disorders, who typically feel controlled by external entities. In addition, dissociative patients may experience strong affects or impulses that feel as if they are imposed on them and are not their own feelings or desires.

Passive influence experiences are a central component of spirit possession, which is a core feature of a number of religious traditions. Possession typically takes either a divine or a demonic form. In the divine form in Western religions, the individual usually feels as if he or she is a passive vessel filled and moved by the Holy Spirit and he or she is serving as an instrument of divine will. There is typically a powerful affective memory of this experience, which may be life-changing. In African, Caribbean, and South American cultures, the individual may become a divine entity, with distinctive speech and demeanor. Often, this god issues commands and pronouncements or bargains with relatives and friends about its terms for relinquishing possession of the body. The individual is typically amnesic for the duration of the possession.

Demonic possession likewise occurs in both Western and non-Western cultures and typically takes the form of an evil entity either attempting to seize physical control or tormenting the individual into doing something against his or her will. In Western cultures, the individual is typically aware of this possession and feels as if he or she is in a

physical struggle with the evil entity, “wrestling with demons.” In non-Western cultures, the individual is often amnesic for these experiences. Possession experiences often occur in the context of a personal crisis and frequently serve in some fashion to alter the individual’s life circumstances in ways that reduce stress. Although more common than generally appreciated, demonic possession is typically treated by religious rituals and thus rarely encountered in clinical settings.

CLINICAL AND RESEARCH MEASURES OF DISSOCIATION

Dissociation Scales and Diagnostic Interviews

Dissociation screening measures and scales have proliferated in the past decade. The best of these instruments equal the levels of reliability and validity established for measures of depression, anxiety, and Posttraumatic Stress Disorder (PTSD). Measurement of dissociation has proven particularly important to understanding the clinical contribution of dissociation to trauma-associated disorders as well as for laboratory studies. Many of these measures are in the public domain and available on the Internet. Establishing the provenance of a given measure downloaded from the Internet is critical to ensuring that a properly validated version is being used, as, unfortunately, some measures have been significantly modified and then reposted under their original name.

Symptom Screening Measures

A number of general dissociation screening scales exist. The Dissociative Experiences Scale (DES), developed by Bernstein and Putnam in the mid-1980s, is the most widely used and has been included in hundreds of studies (Bernstein & Putnam, 1986; E. B. Carlson & Putnam, 1993). The 28 items primarily focus on amnesias, identity alteration, depersonalization, derealization, and absorption. The overall DES score can range from 0 to 100. Using receiver operating characteristics methodology, multiple studies converge on DES scores of 30 or greater as a threshold for identifying pathological levels of dissociation (Waller, Putnam, & Carlson, 1996). An overall DES score of 30 or a score of 30 on the 8-item DES-T (taxon; see later discussion) is typically used by studies dividing a sample into high- and low-scoring subjects. Highly correlated with other dissociation measures, the DES has excellent coefficients of internal and test-retest reliability across multiple studies. A trifactorial solution with subscales for amnesia,

depersonalization, and absorption is typically found with clinical samples, whereas general population samples often yield a one-factor solution with absorption items loading most strongly. Within reason, gender, socioeconomic status, and IQ do not appear to have significant influence on DES scores. Translated into over 40 languages, DES studies across cultures reveal strong similarities for both Western and non-Western samples, attesting to the universality of the core constructs of dissociation.

Developed by Marmar, Weiss, and colleagues (1994), the Peritraumatic Dissociative Experiences Questionnaire (PDEQ) assesses dissociative experiences at the time of the traumatic event. A 10-item self-report version (PDEQ-10-SRV) is widely used for both research and clinical screening. A meta-analytic study established that peritraumatic dissociation is the single best predictive factor for the subsequent development of PTSD (Ozer, Best, Lipsey, & Weiss, 2003). Many of the somatosensory and conversion symptoms common in dissociative patients, which include motor inhibitions, loss of function, anesthetics and analgesias, pain, and problems with vision, hearing, and smell, are tapped by the Somatoform Dissociation Questionnaire (SDQ-20) developed by Nijenhuis (1999). Whereas the 20-item version (SDQ-20) has good reliability and validity for discriminating Dissociative Disorder patients, a 5-item version (SDQ-5) can serve as a quick screening measure. Administered by a trained rater, the Clinician Administered Dissociative States Scale (CADSS) by Bremner et al. (1998) has proven useful in laboratory studies of acute dissociative states for assessing symptoms of amnesia, depersonalization, and derealization.

For children and adolescents, three primary measures have been used most widely. A parent/caretaker/teacher 20-item report measure, the Child Dissociative Checklist (CDC), is a reliable and valid screen for dissociation in children 5 to 12 years of age. Rating each behavior on a 3-point scale, scores can range from 0 to 40, with scores of 12 or greater indicative of pathological levels of dissociation. Several investigators have identified items of the ever popular Child Behavior Checklist (CBCL) that load on a dissociative subscale. These CBCL dissociation subscales have proven useful in research studies, although the clinical utility has yet to be tested with dissociative patients (Becker-Blease et al., 2004). An adolescent version of the DES, the Adolescent Dissociative Experiences Scale (ADES), measures similar constructs of amnesia, identity alteration, depersonalization, and derealization using age-appropriate item content. A 30-item instrument, the ADES uses a 0 to 10 answer format and has good reliability and validity both as a research tool and as a clinical screening instrument (Armstrong, Putnam, Carlson, Libero, & Smith, 1997; Bo-

nanno, Noll, Putnam, O'Neill, & Trickett, 2003; Brunner, Parzer, Schuld, & Resch, 2000; Fehon, Grilo, & Lipschitz, 2001; Friedrich et al., 2001; Kisiel & Lyons, 2001; Noll, Horowitz, Bonanno, Trickett, & Putnam, 2003).

Diagnostic Interviews

Two structured, *DSM*-based diagnostic interviews have been developed: the Structured Clinical Interview for *DSM-IV* Dissociative Disorders-Revised (SCID-D-R) and the Dissociative Disorders Interview Schedule (DDIS). Developed by Marlene Steinberg (1994), the SCID-D-R is widely regarded as the gold standard for research studies. A semistructured, clinician-administered interview, the SCID-D-R assesses the presence and severity of amnesias, identity confusion/alteration, depersonalization, and derealization and renders a *DSM-IV* diagnosis for all five dissociative disorders as well as for Acute Stress Disorder. Administration time for the 276 questions typically ranges from 1 to 2 hours for Dissociative Disorder patients. Interrater and test-retest reliability is good to excellent and validity is well established in numerous studies. Translated into at least a dozen languages, it yields largely similar results in different cultures.

Ross's (Ross, Heber, et al., 1989) DDIS is primarily a clinical diagnostic instrument but is sometimes used as a screening measure. Inquiring about a wide range of phenomena in addition to dissociative symptoms, the DDIS also includes questions about child abuse history, Major Depression, somatic complaints, substance abuse, and paranormal experiences. This instrument requires about 60 minutes to administer to DID patients. Interrater reliability is regarded as acceptable for all dissociative disorders except Depersonalization Disorder, and convergent validity includes strong correlations with the DES and with clinical diagnoses of dissociative disorders.

DSM DISSOCIATIVE DISORDERS

Dissociative Amnesia

History and Epidemiology

Researchers are increasingly looking at the prevalence of dissociative amnesia, originally studied in combat samples, in cases of sexual abuse, physical abuse, and emotional abuse. During World War II, prevalence rates for dissociative amnesia ranged from 5% to 14.4%, with only a small percentage reported to have suffered significant head injuries. In one study of 1,000 soldiers exposed to intense combat, 35% had amnesia. In soldiers with minimal

battlefield exposure, past or family history of dissociation or "hysterical" symptoms was associated with dissociative amnesia.

Dissociative Amnesia was found in approximately 6% of a stratified, general population survey sample in Winnipeg, Canada (Waller & Ross, 1997). Onset typically begins in late adolescence and adulthood, with no apparent differences across gender. Dissociative Amnesia may be especially difficult to assess in preadolescent children, where it can be difficult to differentiate from daydreaming, inattention, anxiety, oppositional behavior, cognitive limitations, and psychotic disturbances. Adolescents are better able to verbalize their experiences of amnesia and may have personal names for the phenomenon. For example, one teenager said, "I skip time," and another called the experience "flickering." Most individuals describe more than one amnesia episode.

Over 70 studies have examined dissociative amnesia in child abuse samples using clinical, community, and forensic populations, including retrospective, prospective, and longitudinal study designs. In various studies of clinical populations and individuals who identified themselves as survivors of abuse, 16% to 90% reported amnesia for the abuse at some time in their lives, averaging about 20% across studies. In studies of college undergraduates and women in the community, prevalence of amnesia for abuse ranged from 13% to over 50%. A study by Goodman et al. (2003) using children whose cases were accepted for prosecution and who therefore were highly likely to recall their sexual abuse, having already repeatedly described it to police and district attorneys, found that 19% were unable to recall the target episode. Failure to recall the target episode was correlated significantly with dissociation scale scores. To date, every study that has investigated the existence of amnesia for sexual abuse has found a nontrivial percentage of subjects reporting that at some time in their lives they were not able to recall the sexual abuse or were not aware of having been sexually abused until they "remembered it" many years later.

Diagnosis

The essential feature of Dissociative Amnesia, according to the *DSM-IV-TR*, is the inability to recall important personal information, usually of a traumatic or stressful nature, that is too extensive to be explained by normal forgetfulness (American Psychiatric Association, 2000).

More broadly defined, Dissociative Amnesia is a reversible memory impairment in which groups of autobiographical memories that would ordinarily be available for recall cannot be retrieved or retained in a verbal form (or, if temporarily retrieved, cannot be wholly retained in consciousness). Although this amnesia may result from trauma-related changes in the brain, gross destruction of

brain structures that subserve memory does not occur, and the disorder expresses itself as a potentially reversible form of psychological inhibition.

The diagnosis of Dissociative Amnesia generally connotes four factors: (1) Relatively large groups of memories and associated affects have become unavailable, not just single memories, feelings, or thoughts; (2) the unavailable memories usually relate to day-to-day information that would ordinarily be a more or less routine part of conscious awareness: who I am, what I did, where I went, what happened, whom I spoke with, what was said, what I thought and felt at the time, and so on; (3) the ability to remember new factual information, general cognitive functioning, and language capacity are intact; and (4) the dissociated memories often indirectly reveal their presence in more or less disguised forms such as intrusive visual images, flashbacks, somatoform symptoms, nightmares, conversion symptoms, and behavioral reenactments. Dissociative Amnesia is part of a larger spectrum of memory dysfunction related to traumatic stress.

Dissociative Amnesia presents in two basic forms. The first is a dramatic onset of amnesia for extensive and/or important personal information. These patients are often brought to emergency rooms by police and usually cannot recall their name, age, marital status, and other information central to one's identity. During the acute episode, their behavior may include disorientation, perplexity, alterations in consciousness, and aimless wandering. Despite being frequently portrayed in the popular media, this presentation is relatively rare.

An inability to recall significant aspects of one's personal history is a common form of Dissociative Amnesia. Most patients with Dissociative Amnesia do not complain about this, and it is often discovered only while taking a careful life history. Dissociative amnesic gaps are frequently clearly demarcated in the individual's mind so that he or she is aware of a significant discontinuity in memory. For example, although having clear memory for earlier and later school years, a patient reported that she did not "remember being in sixth grade." Such symptoms are usually associated with traumatic circumstances. It was reported that during the sixth grade, she was kidnapped for several months by her estranged father in a custody dispute and sexually abused by him. A few individuals may deny recall of their entire childhood or other major life epochs.

Treatment

Approaches to the treatment of Dissociative Amnesia have been swept up in the controversy about its existence. Crit-

ics have accused therapists of using "recovered memory therapy" in which they "implant false memories" of sexual abuse or other fictitious trauma. There is scientific evidence that pseudomemories can be created with therapeutic techniques such as hypnosis or narcosynthesis, so therapists should be well versed in appropriate nonsuggestive approaches to facilitating the therapeutic processing of traumatic material (Putnam, 1997). Nonetheless, all of the currently endorsed, evidence-based trauma therapies include a cognitive processing component in which traumatic memories are examined, distortions are corrected, and new and hopeful life meanings are constructed (Foa, Keane, & Friedman, 2000).

In individuals presenting clinically with Dissociative Amnesia or Dissociative Fugues, hypnosis can be a useful adjunct to recalling personal information such as name and life circumstance. Having been involved in over a dozen such acute cases, I have found that hypnosis can be very useful in helping persons recall who they are. The directly verifiable information obtained in this fashion has always been essentially correct, demonstrating that hypnosis may facilitate the accurate recall of dissociated identity and other pertinent information in such cases. Once an individual's identity has been established, arrangements can be made for an extended treatment, which may focus on the acute traumatic precipitant and/or the more extensive prior traumatic history that is strongly associated with a propensity to experience dissociative amnesia or fugue episodes. The second presentation of Dissociative Amnesia, the extended autobiographical gap in memory for often traumatic experiences, is best addressed in a psychotherapy setting using nonsuggestive approaches and generally does not require the use of hypnosis or narcosynthesis. If there is a possibility that the memories recalled during treatment may be used in a legal proceeding, every effort should be made to document that they were recalled in a nonsuggestive fashion, and hypnosis and other techniques should be avoided. In forensic cases, videotaping the interview is usually the best way to document how the interview was conducted, what questions were asked, and the specific responses elicited.

Dissociative Fugue

Dissociative Fugue is the least understood of the dissociative disorders. As defined by the *DSM-IV-TR*, the essential feature is a sudden, unexpected travel away from home or one's customary place of daily activities, with inability to recall some or all of one's past (Criterion A). This is accompanied by confusion about one's identity, sometimes with the assumption of a new identity (Crite-

rion B). Dissociative Fugue may not occur exclusively during the course of DID or be due to the direct physiological effects of a substance or a general medical condition (Criterion C). Dissociative Fugue symptoms must cause significant distress or impairment in social, occupational, or other important areas of functioning (Criterion D).

History and Epidemiology

Charcot (Putnam, 1989) described a number of cases of dissociative fugue, which he divided into an epileptic, traumatic, or hysterical etiology. In the United States, William James (1890) described one of the classic cases of fugue, that of Ansel Bourne. Bourne was an itinerant preacher who disappeared from his home in Providence, Rhode Island. After withdrawing \$500 from his bank account to pay some bills in January 1887, Bourne “awoke” 2 months later. He found himself in Norristown, Pennsylvania, where he had been living quietly under the name of A. J. Brown and working as a shopkeeper. Subsequently, he had no memory for the time between his disappearance and his awakening in the Bourne identity. Under hypnosis, he could describe his activities during the fugue but was not able to retain this information during normal consciousness. As is often the case during a fugue, Bourne apparently behaved normally and did not attract attention to his situation.

Janet (Janet, 1890) also described cases, hypothesizing that fugues involve the dissociation of more complex groups of mental functions than occurs in amnesia and that they are organized around a powerful emotion or feeling state that is linked to many mental associations, all of which are accompanied by a wish to run away. Military psychiatrists described many cases of Dissociative Fugue in both World Wars.

No cases of Dissociative Fugue were diagnosed in the single epidemiological study of dissociative disorders conducted to date. Fugues are thought to be more common during natural disasters, wartime, or times of major social dislocation and violence, although no systematic data exist on this point. Pre-*DSM-III* cases are often difficult to assess as prior diagnostic criteria were sometimes quite different. Most case reports describe males, primarily in military samples, but insufficient data exist to document a gender bias to this disorder. Fugue is usually described in adults, but adolescent cases have been reported.

Diagnosis

The underlying cause of most fugue episodes is thought to be overwhelming or traumatic circumstances, which pro-

duce an altered state of consciousness dominated by a wish to flee and forget. Fugues have been linked to combat, rape, recurrent childhood sexual abuse, massive social displacements, and natural disasters. In cases where there is not an immediate traumatic precipitant, there is often an antecedent history of serious trauma or social disruption. In these cases, individuals were usually struggling with extreme emotions or impulses such as overwhelming fear, guilt, shame, and/or intense incestuous, sexual, suicidal, or violent urges.

Dissociative fugues have been reported to last from minutes to months, with some individuals reporting multiple fugues. In some severe cases of PTSD, nightmares may terminate in a fugue in which the patient runs outside or elsewhere. Classically, three types of fugue have been described: (1) fugue with awareness of loss of personal identity; (2) fugue with change of personal identity; and (3) fugue with retrograde amnesia. During a fugue, individuals most often do not attract attention or exhibit overt psychopathology. Occasionally, some individuals display bizarre, disorganized, or dangerous behavior, such as a soldier who begins a fugue episode by standing up and walking away, exposing himself to intense enemy fire. Following termination of a fugue, the person may experience perplexity, confusion, trance-like behaviors, depersonalization, derealization, and conversion symptoms, in addition to amnesia for the events of the fugue. Some patients terminate a fugue with an episode of generalized Dissociative Amnesia. They may be brought to public attention in an attempt to discover who they are and from where they have come.

Dissociative Fugue can be differentiated from Dissociative Amnesia in that individuals with Dissociative Amnesia may engage in confused wandering during an amnesia episode. In Dissociative Fugue, there is *purposeful* travel away from the individual's home or customary place of daily activities, and usually the individual is preoccupied with a single idea accompanied by a wish to run away from some stressor. Patients with DID may have symptoms of dissociative fugue, usually recurring throughout their lives. Some complex-partial seizures patients wander or exhibit semipurposeful behavior during seizures or postictally, for which there is amnesia. In an epileptic fugue, however, individuals often exhibit abnormal behavior, including confusion, perseveration, and abnormal or stereotypic movements. A variety of general medical conditions, toxic and substance-related disorders, delirium, dementia, and organic amnestic syndromes may give rise to random wandering. In most cases, however, the somatic, toxic, neurological, or substance-related etiology can be identified by history or by physical and laboratory findings.

Treatment

An eclectic, psychodynamically informed psychotherapy focused on helping the patient recover memory for identity and recent experience is the recommended treatment for Dissociative Fugue. Adjunctive techniques such as hypnotherapy and pharmacologically facilitated interviews to assist with memory recovery are frequently necessary. Therapy should be carefully paced to avoid overwhelming the individual with traumatic material. Clinical stabilization, safety, and a therapeutic alliance using supportive and educative interventions constitute the initial phase. Once stabilization is achieved, subsequent therapy is focused on helping the patient regain memory for identity, life circumstances, and personal history. During this period, extreme emotions and/or severe psychological conflict related to trauma may emerge. A supportive and nonjudgmental stance, especially if the fugue has been precipitated by intense guilt or shame over an indiscretion, is an important therapeutic element. Simultaneously, it is important for the therapist to balance this stance with helping the patient take realistic responsibility for misbehavior that may have occurred.

Dissociative Disorder Not Otherwise Specified

All of the conditions characterized by a primary dissociative response that do not meet diagnostic criteria for one of the *DSM-IV-TR* dissociative disorders are covered under the catch-all diagnosis of DDNOS. Dissociative Disorder Not Otherwise Specified is a heterogeneous collection of dissociative reactions, some of which are common expressions of distress in other cultures but relatively rare in Western societies. Included in DDNOS are the many cultural variants of dissociative trance. Anthropologists have identified forms of dissociation in every culture that they have examined. In some instances, this takes the form of specific trance-state disorders; in others, it is manifest in religious rites and rituals; and in still others, in the form of traditional healing practices. All of these forms of dissociation are common in many non-Western societies. Increasingly, measures such as the DES and SCID-D are being adapted for these cultures and used to investigate these conditions.

The *DSM* also includes under DDNOS those dissociative reactions elicited by coercive persuasive practices such as torture, brainwashing, thought reform, mind control, and indoctrination intended to induce an individual to relinquish basic political, social, or religious beliefs in exchange for antithetical ideas and beliefs. Finally, Ganser's syndrome, a rare and poorly understood condition, character-

ized by the giving of approximate answers is also included in this category.

Dissociative Trance Disorder

Dissociative Trance Disorder is manifest by a temporary, marked alteration in the state of consciousness or by loss of the customary sense of personal identity without the replacement by an alternative sense of identity. There is often a narrowing of awareness of the immediate surroundings or a selective focus on stimuli within the environment and/or the manifestation of stereotypic behaviors or movements that the individual experiences as beyond his or her control. A variant of this, Possession Trance, involves single or episodic alternations in the state of consciousness characterized by the exchange of the person's customary identity with a new identity, usually attributed to a spirit, divine power, deity, or another person.

The best described example of the dissociative trance-state disorder form of DDNOS is *Ataque de nervios* (Lewis-Fernandez et al., 2002; Schechter et al., 2000). *Ataque de nervios* is characterized by somatic symptoms such as fainting, numbness and tingling, fading of vision, seizure-like convulsive movements, palpitations, and sensations of heat rising through the body. Individuals may moan, cry out, curse uncontrollably, attempt to harm themselves or others, or fall down and lie with death-like stillness. During an episode of *Ataque de nervios*, there is a narrowing of consciousness and lack of awareness of the larger environment. Following an episode, the individual typically has partial or full amnesia for the events and his or her actions. Attacks may occur only once, be episodic, or occasionally become chronically recurring with significant functional impairment. DES scores were correlated with frequency of episodes in one study (Lewis-Fernandez et al., 2002).

Family, marital, or other interpersonal conflicts or losses are the most common precipitants of *Ataque de nervios*. Alcohol, physical or sexual violence, financial loss, or stress and fear may also trigger an attack. Histories of physical and sexual abuse are commonly reported but are not strongly correlated with severity or frequency of episodes. A sense of being overwhelmed, hopeless, and helpless often evokes an episode. This is followed by an abrupt narrowing of consciousness and the appearance of more florid symptoms. Attacks are usually a few hours in duration but can last from minutes to days.

Brainwashing, Mind Control, Thought Reform

The concept of brainwashing, mind control, or thought reform emerged from the Korean conflict after some Ameri-

can prisoners of war made anti-American statements. A journalist, Edward Hunter (later identified as a CIA agent), proposed that the Chinese Communists had discovered techniques to modify mental attitudes and beliefs, a process he called brainwashing. Following the Armistice, a team of psychiatrists and psychologists interviewed the returning prisoners and concluded that they had not been subjected to a systematic thought reform program. Rather, the statements were the result of rewarding severely deprived prisoners with food and warm clothing, but their basic attitudes had not, in fact, been altered. However, the subsequent release of another group of prisoners (missionaries, businessmen, doctors, and students) caught in China at the beginning of the war did seem to suggest that some form of thought reform had occurred with these individuals, several of whom continued to falsely insist that they were spies.

In the late 1960s and 1970s, allegations of brainwashing or mind control resurfaced in the context of counterculture religious movements. Dr. Louis (Jolly) West (West & Singer, 1980), who consulted on the famous case of Patty Hearst, the heiress who was kidnapped, tortured, sexually abused, and held in prolonged solitary confinement, was largely responsible for the reintroduction of this concept. After prolonged isolation and mistreatment, Hearst developed another identity, the revolutionary Tania, who aided her captors in criminal acts, including bank robbery and murder. Margaret T. Singer (West & Singer, 1980), a psychologist associated with West, subsequently widely publicized her ideas about “conditioning techniques” that she believed were used by religious cults to render their members incapable of complex rational thought and unable to make decisions. In a series of lawsuits by ex-cult members, she testified that these techniques were capable of overpowering a person’s free will and that the group’s control over a member could be total. The notion that brainwashing was a common practice in religious cults was popularized by media coverage of these sensational trials.

A group of academics, primarily psychologists and sociologists, subsequently challenged Singer, pointing out that individuals who joined cults often came from dysfunctional families. Marc Galanter (Galanter, 1982), a psychiatrist involved in some of these cases, reframed the religious cult mind control debate by advocating the more neutral term “charismatic religious sects.” He pointed out that an individual’s behavior in such a social group may reflect psychological adaptation rather than psychopathology. The manner of leaving the group, voluntarily or by being kidnapped and involuntarily deprogrammed, was a significant predictor of an individual’s report of whether he or she had been brainwashed, with the latter the most likely to express this belief. In the context of a particularly sensational case (Molko vs. Holy Spirit Association), the American Psycho-

logical Association and the American Sociological Association submitted amicus briefs refuting the concept of brainwashing as lacking scientific validity. This served to nullify its legal status as a legal defense. Although the academic community has largely avoided the subject, the notion of brainwashing continues to fascinate the public and to be invoked by a few psychotherapists and others as evidence of occult or government conspiracies.

Ganser’s Syndrome

Ganser’s syndrome is a poorly understood condition, reclassified from a factitious disorder to a dissociative disorder in the *DSM-III*, characterized by the giving of approximate answers (paralogia) together with a clouding of consciousness and frequently accompanied by psychogenic somatic or conversion symptoms (Andersen, Sestoft, & Lillebaek, 2001). The symptom of “passing over” (*vorbeigehen*) the correct answer for a related but incorrect one is the hallmark of Ganser’s syndrome. The approximate answers often just miss the mark but bear an obvious relation to the question, indicating that it has been understood. For example, when asked how old she was, a 25-year-old woman answered, “I’m not 5.” Another patient, when asked how many legs a horse had, replied, “Three.” If asked to do simple calculations (e.g., $2 \times 2 = 5$) or for general information (capital of the United States is New York) or to identify simple objects (a pencil is a key) or to name colors (green is gray), these individuals give erroneous but comprehensible answers.

There is also a clouding of consciousness, usually manifest by disorientation, amnesias, loss of personal information, and some impairment of reality testing. Visual and auditory hallucinations occur in roughly half of the cases. Many of the case reports include histories of head injuries, dementia, or organic brain insults. Neurological examination may reveal what Ganser (Ganser, 1898) called “hysterical stigmata,” for example, a nonneurologic analgesia or shifting hyperalgesia. Many authorities make a distinction between Ganser’s symptoms of approximate answers, which may occur in a number of psychiatric and neurological conditions, and Ganser’s syndrome, which must be accompanied by other dissociative symptoms such as amnesias, conversion symptoms, or trance-like behaviors.

Dissociative Identity Disorder

Diagnosis

Dissociative Identity Disorder, formerly Multiple Personality Disorder, is the best researched of all the dissociative disorders. In many respects, it is the paradigmatic

dissociative disorder in that the symptoms of all the other dissociative disorders are common, including amnesias, fugues, depersonalization, derealization, and possession-like experiences.

The *DSM-IV-TR* defines DID as characterized by “the presence of two or more distinct identities or personality states” that “recurrently take control of the person’s behavior,” accompanied by an “inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness” (American Psychiatric Association, 2000, p. 529). These identities or personality states—sometimes called “alters,” “self states,” “alter identities,” or “parts”—differ from one another in that each presents as having “its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self.”

History and Epidemiology

During the nineteenth century there was a lively academic interest in dual and multiple personality cases, which stimulated a larger public awareness that was shaped in large part by often inaccurate artistic and general media representations. Multiple personality became a common plot device in pulp thrillers as well as part of the larger public interest in mysticism, mediumship, and the occult that flourished at the end of the century. Although some nineteenth-century case reports include paranormal features, most are fairly straightforward clinical accounts, which typically resemble today’s cases.

By the 2nd decade of the twentieth century, the study of DID had begun to wane. Authorities suggest a variety of factors contributing to this loss of interest, including the rising dominance of Freudian paradigms of hysteria, the disrepute into which hypnosis fell at this time, the rise of Bleuler’s then newly coined diagnosis of Schizophrenia, which specifically included dissociative patients, and a loss of interest in the works of Janet, Prince, and others who had been so crucial in the development of models of dissociation. Morton Prince observed that their ideas were being drowned by the rising tide of psychoanalysis, which he regarded as antithetical to the concept of dissociation (cited in Hale, 1975).

Although scattered multiple personality cases continued to be reported in reputable journals in the 1930s to 1960s, most notably the famous “The Three Faces of Eve,” (Thigpen & Cleckley, 1957) it was not until the 1970s that systematic research was again undertaken. The modern era begins with the work of Arnold Ludwig and colleagues (Larmore, Ludwig, & Cain, 1977; Ludwig, 1983; Ludwig, Brandsma, Wilbur, Bendfeldt, & Jameson, 1972) at the University of Kentucky during the 1970s. These studies in-

cluded systematic comparisons of psychophysiological and neurocognitive measures across the alter personality states of individuals with Multiple Personality Disorder. Beginning in the 1980s, researchers in North America, Europe, Turkey, Japan, and elsewhere began systematic research studies on the phenomenology, epidemiology, psychobiology, and treatment of DID in adults, children, and adolescents. Despite the thousands of cases described in the world’s literature and the hundreds of scientific papers on multiple personality and dissociation, controversy continues over the validity of the disorder, with a vocal minority of clinicians subscribing to an iatrogenic explanation for multiple personality.

The best epidemiological data available for multiple personality come from the Winnipeg stratified sample ($n = 1,055$) study by Ross, Joshi, and Currie (1989). This yielded a prevalence rate of 3.1%, although a more conservative reanalysis of these data suggests a prevalence of about 1.3% for DID. An independent analysis of the DES data collected on the same sample yielded a prevalence rate of 3.3% for “pathological dissociation,” a construct including DES items for amnesia, depersonalization, derealization, identity confusion and alteration, and inner voices (pseudohallucinations), a symptom profile typical of clinical DID patients (Waller & Ross, 1997). A second epidemiological study of a community sample ($N = 1,007$) in Memphis, Tennessee, found that although dissociative symptoms were common, only 2% scored in the Taxon level on the DES-II (Seedat, Stein, & Forde, 2003). Higher dissociation levels were associated with male gender, minority status, and harmful alcohol consumption, all variables associated with higher incidence of risk for dissociative disorders and for traumatic experiences.

The prevalence rate of DID in general psychiatric patient samples has been investigated by several studies using the SCID-D or DDIS structured diagnostic interviews (Putnam, 1997). Across these studies, including samples from the United States, Canada, Turkey, and several western European countries, an average of 5% to 15% of adult psychiatric inpatients meet *DSM* criteria for DID. Higher rates were found in substance abuse treatment populations and inpatient adolescents.

Gender differences in the frequency of DID have long been noted. Clinical studies generally include 5:1 to 9:1 female to male ratios. Interestingly, research with measures such as the DES finds no evidence of gender differences in the propensity or capacity to dissociate. Developmental studies indicate that the ratio of female to male DID cases steadily increases from 1:1 in early childhood to about 8:1 by late adolescence (Putnam, Hornstein, & Peterson, 1996).

A number of reasons have been proposed for the increased numbers of female DID patients, including gender-related differences in the types, age of onset, and duration of maltreatment experienced by males and females; differences in clinical presentations such that male cases are more likely to be missed; and the possibility that more male DID cases end up in the criminal justice and/or alcohol and drug treatment systems rather than the mental health system.

Dissociative Identity Disorder is strongly linked to experiences of severe, early childhood trauma, usually maltreatment. All studies, in both Western and non-Western cultures, that have systematically examined this link have documented this relationship. Across a wide variety of studies, the reported rates of severe childhood trauma for both child and adult DID patients range from 85% to 97% of cases. The most frequently reported sources of childhood trauma in clinical research studies are physical and sexual abuse, usually in combination. Other kinds of trauma have also been reported, including painful medical and surgical procedures and wartime trauma. Critics have raised questions about the validity of DID patients' self-reports of childhood trauma. Recent studies, including large samples of maltreated children with dissociative disorders and intensively validated case studies, have provided rigorous independent corroboration of the patients' reports of maltreatment (Hornstein & Putnam, 1992; Lewis, Yeager, Swica, Pincus, & Lewis, 1997). These studies continue to strongly support a developmental link between childhood trauma and DID.

Evaluation of Memory and Amnesia Symptoms

Dissociative disturbances of memory are manifest in several basic ways and are frequently observable in clinical settings. Clinicians should routinely inquire about experiences of "losing time," blackout spells, and major gaps in the continuity of recall for personal information. These experiences are rarely spontaneously reported by patients, who often consider them to be evidence of "craziness." Thus, active inquiry by the interviewer is necessary to uncover amnesia. The clinician should ask for specific examples when the patient acknowledges a symptom such as time loss. Sometimes, patients describe "coming to" or "waking up" in the middle of an activity with little or no recall of how they came to be there. At other times, patients find evidence of having done or acquired things for which they have no memory. Family members and friends may tell them about significant things that they have said or done for which they have no recall. They may have traveled to some unexplained place (a fugue episode) or may not be able to remember what they did for days or even weeks.

Dissociative time loss experiences are too extensive to be explained by normal forgetting. Typically, they have clearly demarcated beginnings and endings. It is important to establish that such time loss experiences are not associated with drug or alcohol use. Unfortunately, the high comorbid rates of drug and alcohol abuse in dissociative patients complicates this determination.

Perplexing fluctuations in skills, habits, or well-learned abilities such as fluency in a foreign language or athletic abilities are common in patients with severe dissociative memory disturbances. Patients report the experience of "all of a sudden drawing a complete blank" for skills or knowledge, whereas at other times the skills are present and the information is easily and reliably recalled. This "perplexing forgetfulness" is thought to relate to the state-dependent disturbances of implicit memory functions noted in experiments with dissociative patients (Bremner, Krystal, Southwick, & Charney, 1995; DePrince & Freyd, 1999, 2001; Dorahy, 2001; Eich, Macaulay, Loewenstein, & Dohle, 1997).

Significant gaps in autobiographical memory, particularly for childhood events, are often reported for dissociative patients. The historical gaps are usually sharply defined and do not fit the normal, age-related decrease in memory for events of younger ages. In dissociative patients, recall of autobiographical memories may have a depersonalized quality such that recalled events are likened to recalling a dream or as if they had happened to someone else.

Dissociative Process Symptoms

Dissociative process symptoms include depersonalization and derealization, dissociative hallucinations, passive influence/interference experiences, and dissociative cognition. Some authorities also include dissociative alterations in identity. Depersonalization and derealization are commonly reported by DID patients, as well as out-of-body experiences. Patients frequently describe feeling "spaced out" or cut off from themselves and others. There is a distant or unreal, hazy or foggy quality to the world at large. Patients may liken it to being in a dream. Out-of-body experiences commonly take the form of watching oneself from a great distance. The observer's point of view may be experienced as either internal or external to the patient. That is, some patients report a sense of an internal distance, as if watching from "somewhere way back in my head." Experiences of watching oneself do something—often dangerous—but being unable to stop one's actions are also common.

Dissociative auditory hallucinations typically take the form of voices heard in one's head (sometimes called

pseudohallucinations), as opposed to voices coming from the environment. Dissociative hallucinations typically have distinctive qualities of age, gender, and affect that mark them as individual. The voices may comment negatively about the patient, argue with each other, or command the patient to perform certain acts. They also have secondary process characteristics in that they may, at times, discuss neutral topics with the patient, provide useful information, or support and comfort during stressful experiences. Patients usually recognize the voices as hallucinations, but they may be reluctant to disclose their existence for fear of being considered psychotic. Unless they are stressed, many patients report some capacity to ignore or disregard hallucinations. Over the course of treatment, specific alter personality states often come to be identified with specific hallucinated voices. Visual hallucinations typically take the form of graphic images, usually having traumatic or frightening content. Tactile, somatic, and olfactory “hallucination-like” experiences can occur in DID patients, leading to misdiagnosis of other neurological disorders (Devinsky, Putnam, Grafman, Bromfield, & Theodore, 1989).

Cognitive Impairments

The recognition that dissociative patients frequently manifest subtle, but often clinically significant, cognitive impairments emerges from clinical research with psychological and cognitive test batteries. Research using projective testing finds distinctive cognitive process markers, including evidence of confusing and contradictory responses to the same stimulus. Distinctive responses to standardized projective testing can often be helpful in distinguishing dissociative patients from other diagnostic groups, such as patients with affective disorders, nondissociative forms of PTSD, personality disorders, psychotic disorders, and factitious disorders (Armstrong, 1996; Armstrong & Loewenstein, 1990; E. B. Carlson & Armstrong, 1994).

Silberg (1996b) has described specialized approaches to psychological and cognitive testing in children and adolescents. A number of behavioral features during testing were observed significantly more often in dissociative children compared with other children admitted to a psychiatric unit. These included forgetting, staring, unusual motor behaviors, dramatic fluctuations, fearful and angry reactions and physical complaints during the testing, and expressions of internal conflict. Test responses included increased images of multiplicity, malevolent religiosity, depersonalized imagery, extreme dichotomization, images of mutilation and torture, and

magical transformation. A discriminant analysis correctly classified 93% of the sample.

Dissociative Alterations in Identity

Odd first-person plural or third-person singular/plural self-references are typical early clinical manifestations of dissociative alterations in identity. Patients may refer to themselves by their own first name or make depersonalized self-references such as “the body” when referring to themselves. When describing traumatic events, they may take considerable referential distance, for example, “The father hurt the body, so she was upset. We tried to protect her, but it didn’t work.” Patients often report a profound sense of concretized internal division or personified internal conflicts between different “parts” of themselves. In many cases, these parts have proper names or are designated by a strong affect, behavior, or function, for example, “the angry one” or “the wife.” Patients may suddenly change the way they refer to others in relation to themselves, for example, “the son” replaces “my son” at some point in the discussion.

“Switching behaviors” occur when DID patients change alter personality states. They may manifest during evaluation or therapy sessions. Intrainterview amnesias, in which the patient does not seem to recall or is very confused about the process and content of that session, are a common manifestation. Switching may be evidenced by abrupt shifts in the train of thought or sudden inexplicable changes in affect or in rapport. Physical signs of switching may be observed in conjunction with shifts in affect. These include pronounced upward eye rolls or bursts of rapid blinking and eyelid fluttering. There are often alterations in the patient’s tone of voice and manner of speaking, posture, and demeanor. When possible indications of dissociation are noted, the clinician should ask nondirective, open-ended questions that seek to clarify what the patient is experiencing and recalling about what just happened. The clinician should try to establish whether the patient can give a coherent and continuous description of their immediately preceding interactions. Significant gaps or confusion should be identified and delineated as much as possible. This is a good moment to inquire whether the patient has experienced similar discontinuities in other contexts. If a patient acknowledges prior experiences, it is important to ask for specific examples, both to make certain that these experiences are sufficiently extensive and complex enough to qualify as dissociative and to get a sense of when such experiences are likely to occur.

The alter personalities of DID patients are best conceptualized as discrete behavioral states, each organized

around a prevailing affect, a sense of self (often including a distinct body image), a set of state-dependent autobiographical memories, and a limited behavioral repertoire. Authorities have long cautioned that alter personalities should not be regarded as “separate people” (Putnam, 1997). Rather, the alter personalities should be conceptualized as relatively stable and enduring patterns of behavior that are largely unintegrated with each other and often in direct conflict. A common, and serious, clinical mistake made by novice therapists is to conceptualize and treat specific alter personalities as if they are distinct individuals with interests that are independent of the person as a whole. The basic therapeutic stance is that all of the alter personalities belong to a greater whole and share a basic set of interests.

This set of alter personality states, frequently referred to as the “personality system,” constitutes the larger personality of the individual. Much of the therapeutic focus is directed toward this larger personality system and thus toward the individual as a whole. The psychological and physiological differences observed among the alter personality states of individuals with DID is a source of continuing fascination. Popular accounts in the media overemphasize the differences among alters. Laboratory studies do support the existence of significant differences; however, much general information and many functions and abilities are shared in common across alter personality states. These shared aspects of function, knowledge, and behavior indicate the fundamental unity of the mental processes of the dissociative individual. This common ground provides a foundation for therapeutic efforts focused on the development of a consciously integrated sense of self in the DID patient.

As a group, DID patients show considerable variability in the complexity and therapeutic tractability of their alter personality systems. For more than a century, clinicians have sought to classify DID patients by differences in the organization and dynamics of alter personality systems. However, the validity of these classifications remains to be proven. Alter personality types that are commonly reported include child alter personalities, internalized persecutory alters who inflict pain and may attempt to kill the individual, and depleted and depressed “host” personality states who function as the primary identity with respect to the world at large. Alter personality states often personify painful psychological issues and frequently occur as polarized pairs representing antithetical positions. Alter personality states representing neutral and conflict-free processes also occur. In many DID patients, almost every aspect of mental life is structured and personified in this form.

Dissociative Identity Disorder is conceptualized as a trauma-based disorder; therefore, it is not surprising that the majority of these patients also meet diagnostic criteria for PTSD either by clinical criteria or by using standardized measures and diagnostic inventories. Depending on the study, 70% to 100% of DID patients have been shown to meet diagnostic criteria for PTSD by *DSM-III-R/IV/IV-TR* criteria. In addition, DID patients commonly exhibit multiple types of psychophysiological, somatoform, and conversion symptoms. For example, across studies, 40% to 60% of DID patients also met diagnostic criteria for Somatization Disorder, and many others will meet diagnostic criteria for Somatoform Pain Disorder and/or Conversion Disorder (Ellason, Ross, & Fuchs, 1996; Sar, Akyuz, Kundakci, Kiziltan, & Dogan, 2004).

Treatment

Course and Prognosis. The natural history of untreated DID is largely unknown. A small number of single case studies of partially treated patients followed up many years later suggests that the disorder becomes less active over time, with a decrease in dramatic dissociative symptoms and diminishing conflicts among the alter personality states. The cases are too few, however, to risk generalization. A few small sample studies of DID cases diagnosed in middle age and in geriatric populations indicate that major dissociative symptoms can persist and/or appear in older patients. Clinical experience suggests that a life course of relapse and remission depending on life circumstances is likely in many untreated or partially treated cases. Patients may also be successful in masking or suppressing symptoms for periods of time, even in the face of considerable stress. This may be mistaken for spontaneous remission of the disorder. There is a great need for better longitudinal characterization of all of the dissociative disorders, but most especially the outcomes for treated and untreated DID.

Shared clinical experience with DID cases suggests to many that there are several distinct subgroups of DID patients. Dissociative Identity Disorder patients range from those who function at quite high levels for long periods of time to those who are severely impaired and whose dysfunctional life trajectories began early in childhood. Both clinical presentation and general prognosis vary to some extent across the life span. Children with diagnosable DID show many dissociative symptoms and behaviors but typically have fewer and less crystallized alter personality states. The alter personalities seen in children are typically less invested in their individuality. Thus, if diagnosed early, children often have an excellent prognosis. Indeed, many children appear to have essentially

spontaneous resolution of their DID when they are removed from abusive and neglectful environments. However, in adolescence, alter personalities typically become more behaviorally and affectively distinct and more aggressively invested in their autonomy. Additional alter personalities, typically thematically associated with life stresses, such as academic, athletic, social, or sexual challenges, may appear; then the intrapersonality system dynamics become more complicated and polarized. Adolescents, as a group, have a poorer short-term prognosis than children or adults. This is, in part, because they are often not invested in their treatment and do not see their dissociative symptoms as a problem. Adolescents, particularly if not deeply engaged in school or work, do not experience the same kinds of negative consequences for the discontinuities in their behavior that adults seeking to keep jobs and raise families encounter. Better outcome with DID adolescents has been reported when the patient's family was successfully engaged in treatment. Young adults usually come to clinical attention in the midst of a crisis and may have significant comorbid affective, somatic, posttraumatic, and substance abuse issues in addition to their core dissociative pathology.

Current approaches to the treatment of DID have evolved considerably over the past 2 decades. A major factor has been the reconceptualization of DID as a complex developmental trauma disorder. In addition, the broad spectrum of functioning seen in DID patients has also been better appreciated. A phasic or stages-of-treatment model, similar to the current standard psychotherapeutic approach for PTSD, is now the standard approach to DID. The phases or stages of treatment include (1) symptom stabilization, (2) a period of focused in-depth attention to traumatic material (which is considered optional in some cases), and (3) a phase of "integration" or "reintegration" in which the DID patient practices new cognitive and emotional regulatory skills in place of dissociative defenses. Obviously, these stages are partly heuristic, and aspects of each may be part of the others.

Outcome Studies. Case reports of successful treatments for DID date back over a century. Systematic outcome studies, however, have only appeared within the past 2 decades. These studies remain largely descriptive, with many methodological confounds. The first such study followed up 20 DID patients an average of 3 years after intake following treatment (Coons, 1986). Many of these patients were in treatment with therapists new to DID. Nonetheless, two-thirds of the clinicians treating these pa-

tients reported moderate to great improvement. Severe re-traumatization at some point during the course of treatment was associated with poorer outcomes. A chart review study of 101 Dutch Dissociative Disorder outpatients found that clinical improvement was related to the intensity of the treatment, with more comprehensive therapies having better outcomes (Boon & Draijer, 1993). Using the DES to track treatment progress of 21 DID inpatients, Ross (1989; Ross, Joshi, et al., 1989) found a significant drop in overall scores over a 4-week hospitalization. To date, the largest and best conducted treatment outcome study reevaluated 54 DID inpatients 2 years after discharge to outpatient treatment (Ellason & Ross, 1997). Overall, there were significant decreases in psychopathology, including the number of Axis I and Axis II disorders. The study also found decreased DES scores, decreased depression on the Beck and Hamilton scales, and decreased dissociative symptoms on all of the subscales of the DDIS. The most improved were patients who were reported to be "integrated" according to specific criteria.

The cost-effectiveness of DID treatment has been the subject of two studies (Loewenstein, 1994; Ross & Dua, 1993). Both found that outcome depends on clinical profile. The most responsive group showed significant remission of symptoms within 3 to 5 years after beginning appropriate treatment. A second DID subgroup, with more alter personalities and more Axis II features, had good outcomes but required more hospitalizations in addition to outpatient treatment. The third group, characterized by the longest period of treatment before DID diagnosis, largest number of alters, and most personality disorder problems, had a more lengthy, more expensive, and more problematic course (Ellason & Ross, 1997). When compared with prior treatment costs for these patients, however, treatment specifically targeting DID symptoms showed significant reductions in overall cost after the 1st year. A secondary finding is that more intensive treatment for DID patients has not only reduced overall psychiatric costs, but also decreased medical costs associated with somatoform symptoms. It should be noted that these are preliminary studies with significant limitations, including the diverse and non-standardized nature of the therapy and lack of comparison groups. Nonetheless, they indicate that many DID patients do improve when treatment is focused on their dissociative symptoms. In the long run, overall treatment costs may be saved by adopting the phasic trauma treatment model for these patients. More and better treatment outcome research for DID is desperately needed, but so far has not attracted the necessary funding.

PSYCHOLOGICAL TRAUMA AND DISSOCIATION: SCIENTIFIC APPROACHES

Janet is credited by many as being the first to recognize the relationship between dissociation and trauma (van der Hart & Friedman, 1989). His insight remained largely unappreciated until almost a century later. In the past 2 decades, research has elucidated multiple lines of evidence linking dissociative disorders with antecedent trauma. In aggregate, these separate lines of evidence constitute a strong case for significant trauma as a necessary antecedent to the development of pathological dissociation.

Clinical Cases

The basic set of these lines of evidence involves quantification of Janet's early clinical observations. For each of the *DSM* dissociative disorders, multiple independent case series exist, including non-Western samples, documenting unusually high rates of trauma in Dissociative Disorder patients (although this linkage is weaker for Depersonalization Disorder). Critics often point out that these studies are retrospective, and thus the accuracy of the reports of trauma cannot be established. However, several case series exist in which the majority of subjects had one or more traumas verified (Coons, 1994; Putnam, Hornstein, et al., 1996). Lewis et al. (1997), for example, were able to independently verify childhood trauma in 12 convicted murderers with DID.

Peer-reviewed studies, now numbering in the hundreds, comparing traumatized and nontraumatized groups have found significantly higher levels of dissociation, as measured by well-validated instruments such as the DES, in the traumatized groups for a variety of types of trauma (van Ijzendoorn & Schuengel, 1996). This finding for many different forms of trauma (e.g., combat, rape, natural and man-made disasters, and child abuse) has been documented for many and varied cultures, indicating the universality of the association between trauma and dissociation. Measures of trauma severity, for example, rape and combat severity scales, are correlated about equally with PTSD and dissociation measures ($r \sim .25$ to $.40$), indicating a weak to moderate dose effect-like relationship. The lack of a stronger correlational relationship between trauma and PTSD and dissociation probably reflects the difficulties in quantifying the subjective elements of traumatic experiences. Although these findings clearly link dissociation with antecedent trauma, they are not sufficient to demonstrate that the trauma actually causes the dissociation.

Thus, numerous lines of independent evidence point toward a causal relationship between trauma and dissociation. Thus far, for all cultures in which it has been investigated, a significant relationship has been found between dissociation and many forms of trauma. In the immediate aftermath of a trauma, significant levels of dissociation appear to predispose an individual to develop PTSD and trauma-related psychopathology, although additional factors involving the psychological appraisal of past trauma appear to be involved. Thus, dissociation may serve as a major mediating process between traumatic experiences and subsequent psychopathology. As a mediating factor, dissociation could serve as an important target for prevention and early intervention efforts. In part, stress-resistant individuals are characterized by a lack of dissociative responses to significant stressors.

Military Stress Studies

Charles A. Morgan and colleagues (2001) have conducted a remarkable series of studies on military special operations units under extremely stressful conditions. These studies are as close as we can ethically come to an experimental model of trauma-induced dissociation (Morgan et al., 2001). Morgan examined the neurobiological and psychological effects of intense stress uniformly applied to drug-free, healthy, nonclinical subjects in units undergoing forms of simulated combat, such as survival school. Stressors included semistarvation, exhaustion, sleep deprivation, lack of control over hygiene and bodily functions, and lack of control over movement, social contact, and communication. In these soldiers, the neuroendocrine stress effects equaled or exceeded those measured in other individuals in life-threatening experiences. There were significant overall and scale item differences between pre- and posttest scores on the CADSS. The greatest effects were for depersonalization items such as looking at the world through a fog, feeling time slow down, and spacing out. Forty-one percent of the variance in health complaints following the stress experience was accounted for by dissociation scores.

The results of Morgan's military studies are congruent with clinical reports of the high frequency of dissociation, especially depersonalization symptoms, in normal individuals exposed to life-threatening stress. The ubiquity of dissociative experiences during extreme stress suggests that other factors, perhaps past traumatic experiences, are involved in the peritraumatic dissociation-PTSD linkage discussed earlier. In the military studies, both pre- and poststress dissociative symptoms were significantly correlated with perceived life threat from a prior trauma. Intense

subjective appraisal of life threat from past trauma was associated with the highest dissociation scores. Interestingly, Special Forces soldiers, a highly traumatized subgroup, had low life-threat appraisals of their past trauma and the lowest pre- to poststress change in dissociation scores. These individuals, who often had horrendous histories of early trauma, nonetheless discounted its severity and impact. The existence of this “stress hardy” group underscores the importance of psychological adaptation to past trauma on responses to current trauma. A significant relationship ($r = .67$) was found between the pre-post change dissociation scores and somatic symptoms. This is compatible with clinical studies reporting significant correlations between somatization and dissociation.

Mediation of Trauma Outcomes

A number of studies now indicate that dissociation serves as a mediator of the relationship between antecedent trauma and subsequent psychopathology, including PTSD, aggression, and other externalizing symptoms (Kisiel & Lyons, 2001; Offen, Thomas, & Waller, 2003; Somer, 2002). Thus, if the level of dissociation is statistically controlled, the strength of the relationship between antecedent trauma and current psychopathology is significantly decreased or disappears. High levels of dissociation may also alter the psychophysiological responses of traumatized individuals to traumatic reminders. Dividing traumatized subjects into high and low dissociative subgroups based on standard scales reveals that high dissociators show lower psychophysiological arousal when confronted with stimuli that are reminiscent of their traumatic experiences (e.g., Griffin, Resick, & Mechanic, 1997). Nonetheless, the high dissociative subjects often report significantly more psychological distress than the low dissociative group, who typically show more classic patterns of hyperarousal for physiological indices such as heart rate and skin conductance. These findings should be considered preliminary and require further replication. These data do indicate that increased dissociation associated with trauma may serve as an important mediating process involved in the transformation of traumatic experiences into subsequent psychopathology.

Sophisticated statistical methods, physiological measures, and brain imaging technologies are now uncovering new lines of evidence indicating that increased dissociation is instrumental in shaping outcomes related to traumatic experience and psychophysiological responses to future stress and trauma. Peritraumatic dissociation, sometimes measured proximal to the trauma and sometimes retrospectively about the trauma, has been found to predict the sub-

sequent development of PTSD in many, but not all, studies (Ozer et al., 2003). Predictive power is both a form of validity and clinically important for identifying individuals at risk for developing PTSD following an acute trauma.

Dissociation in the Laboratory

The experiments of Morton Prince (Prince & Peterson, 1908) using a crude polygraph to measure galvanic skin resistance (GSR) across the alter personality states of a DID patient—a physiological measure that remains of interest today—initiated the scientific study of DID in 1908. Prince recorded differential GSR reactivity responses to words that were emotionally charged for one alter personality but not for another. Several dozen psychophysiological and cognitive performance studies were added to the literature over the next century (Alvarado, 1989). Most of these reported data indicating that DID alter personality states differ in responses to common stimuli. However, the small sample sizes—typically only a single case—and the lack of control subjects limit their credibility. The few better-controlled studies with larger samples generally support the earlier findings of differences across alter personality states. The heterogeneity of research methods and measures together with the often idiosyncratic differential responses elicited in DID subjects have limited opportunities for replication across studies. However, investigation of differential neurobiological responses and differences in cognitive performance across alter personality states of DID patients remain an important source of information about the nature of dissociation.

A new avenue of experimental investigation was opened up with the advent of reliable and valid measures of dissociation. The correlation of scale scores with a variety of physiological, neuroendocrine, cognitive, and brain imaging data facilitates examination of the biological underpinnings of dissociation and the impact of dissociation on physical and mental functioning. The division of subjects into high and low dissociative subgroups has led to the identification of significant differences in physiological and cognitive measures.

Studies with the CADSS document dissociative-like experiences pharmacologically induced in normal controls and in clinical populations such as PTSD patients (Bremner et al., 1998). These studies primarily focus on traumatized individuals who suffer from PTSD or trauma-associated psychopathology but who do not have a dissociative disorder. Laboratory studies using pulsed photo and audio stimulation have induced dissociative symptoms in normal individuals (Leonard, Telch, & Har-

ington, 1999). Subjects scoring higher on pretest dissociation measures show greater effects, although these are well below clinical thresholds. In aggregate, the large numbers of studies including measures of dissociation in their assessment have taught us much of what we have learned in the past decade.

Brain Imaging Studies of Dissociation

Case reports continue to describe EEG differences across DID alter personality states, but investigators are increasingly turning to the newer brain imaging technologies in their efforts to document dissociation. A functional magnetic resonance imaging (fMRI) study of 12 switches among three alter personality states in a single patient found changes in brain activity bilaterally in the hippocampus and in the right parahippocampal and medial temporal regions (Tsai, Condie, Wu, & Chang, 1999). Saxe, Vasile, Hill, Bloomingdale, and van der Kolk (1992) used single positron emission tomography (PET) to scan four alter personality states. The left temporal lobe was the brain region that showed the greatest variation across personality states. Using single PET imaging, Sar, Unal, Kiziltan, Kundakci, and Ozturk (2001) compared 15 DID patients with 8 controls. They reported that the DID patients showed significant hypoactivity bilaterally in the orbitofrontal region and increased left lateral temporal activity. In a PET study of 11 DID subjects who listened to traumatic and neutral scripts in a "traumatic" and "neutral" personality, Reinders et al. (2003) found correlates to two distinct activation states marked by different regional cerebral blood flow patterns. Thus, to date, multiple imaging studies of DID patients have found significant differences across alter personality states, although no signature differences have been identified.

Two studies have focused on the functional imaging of depersonalization. Mathew et al. (1999) infused THC, an active component in marijuana, into 59 normal subjects, who showed significantly increased overall cerebral blood flow with the largest changes in the right hemisphere. Increases in depersonalization were most significantly correlated with increased blood flow in the frontal lobes and anterior cingulate cortex. Using PET imaging with Depersonalization Disorder patients and controls, Simeon and colleagues (2000) found that the patients had lower activity in the right superior and middle temporal gyri and higher activity in the parietal and left occipital cortex. It is difficult to compare these two studies, as one uses healthy controls receiving a psychoactive drug producing mild to moderate feelings of depersonalization and the other uses chronic Depersonalization Disorder patients. They do,

however, suggest that feelings of depersonalization may be detectable with functional brain imaging methods.

In a series of well-conducted, well-controlled studies, Ruth Lanius and colleagues (Lanius, Bluhm, Lanius, & Pain, in press; Lanius, Hopper, & Menon, 2003; Lanius et al., 2002, 2004; Lanius, Williamson, et al., 2003) have conducted the most systematic fMRI investigations of both PTSD and dissociative symptoms in traumatized individuals. Using the script-driven traumatic imagery methodology developed with PTSD patients, they have compared patients exhibiting dissociative responses with those exhibiting hyperarousal responses (Lanius et al., 2002). Compared with the PTSD patients exhibiting hyperarousal, the dissociative subjects had higher brain activation in the superior and middle temporal gyri, inferior frontal gyrus, and occipital and parietal lobes. PTSD patients with hyperarousal responses showed increased heart rate during the traumatic imagery segment, but those with dissociative responses did not.

In a remarkable case study, Lanius and colleagues (Lanius, Hopper, et al., 2003) assessed the fMRI and heart rate responses of a couple who were trapped in their automobile during a massive highway wreck involving over 100 vehicles. The couple witnessed a child burn to death and feared that they would also die. Both met diagnostic criteria for PTSD 4 weeks after the accident, when they participated in a script-driven imagery study. The husband reported a vivid memory for the experience, including his desperate search for an escape route. His heart rate increased dramatically and he manifested increases in brain activity over baseline in the anterior, frontal, anterior cingulate, superior temporal, parietal, occipital, and left thalamic regions. In contrast, his wife reported feeling extremely numb and frozen during the traumatic script segment. Her fMRI showed only a tiny increase in activity in the occipital region and her heart rate did not change. Although their traumatic exposure was about as matched as possible, these two individuals had markedly different subjective responses to a standard traumatic reminder, which were paralleled by distinct differences in brain activation patterns.

In aggregate, imaging studies indicate that there are brain activation markers that distinguish dissociative phenomena from other conditions. In several of the studies, the brain regions showing increases or decreases in metabolic activity were largely overlapping. No definitive dissociative pattern has emerged, however, and much additional research will likely be required before we understand what we are really seeing in these imaging studies. Nonetheless, the fact that dissociative effects can be detected in brain

imaging as well as in physiological and cognitive studies offers an opportunity to trace some of the neural circuitry underlying this powerful process.

Memory and Cognitive Studies

A central feature of the dissociative disorders is their dysfunctions of memory. Prince's original GSR experiment sought to capture the often reported directional amnesias between alter personality states (Prince & Peterson, 1908). Many of the case studies that followed also sought to document these amnesias. Until the 1985 NIMH study by Silberman, Putnam, Weingartner, Braun, and Post, several small case series published by Ludwig, Larmore, and colleagues during the 1970s were the most sophisticated investigations of DID (Larmore et al., 1977; Ludwig, 1983; Ludwig et al., 1972). Silberman et al. used 9 DID patients and 10 matched controls, who were tested as themselves and in a simulated alter personality state. Testing the separateness of memory between pairs of reportedly mutually amnesic alter personality states by measuring intrusions from categorically similar word lists learned by the other alter personality states, Silberman et al. found that "the DID patients were more likely to compartmentalize the stimuli learned, whereas those mimicking dissociation showed far less evidence of information partitioning" (quoted in Dorahy, 2001, p. 778). Preliminary studies suggesting that dissociation had differential impacts on the domains of implicit and explicit memory remain to be replicated (Dorahy, 2001).

Recent studies of memory in DID patients have, however, found that the most salient marker of which information is likely to be available or unavailable across alter personality states is the degree of cognitive processing required for stimulus comprehension and interpretation (Dorahy, 2001). The greater the mental effort required and the more the encoding of that information is biased in some fashion by the "personality" of a given alter personality state, the less likely that information is to transfer to another personality state. Studying the alter personalities of 9 DID subjects with a battery of explicit and implicit memory tests, Eich et al. (1997) concluded that the distinction between explicit and implicit memory was not the critical factor. Rather, it "appears that how much leakage occurs across alter personality states depends on the extent to which encoding and retrieval processes are susceptible to personality-specific factors" (p. 421). Similarly, Peters, Uytterlinde, Consemulder, and van der Hart (1998) substantiated the existence of directional or asymmetric amnesias across alter personality states but did not find performance differences between implicit and explicit memory tests.

The existence of differential and directional amnesias across DID alter personality states have been found in all but one study to date. The more rigorous studies, however, also document considerable leakage or transfer of information across alter personality states, which report being completely amnesic for one another. At the end of the nineteenth century, Ribot (1882) first articulated the most parsimonious neuropsychological explanation put forward thus far: that these amnesias are examples of state-dependent learning and retrieval. The degree of amnesia demonstrated in DID patients, however, exceeds that which is typically seen in experimental studies of state-dependent memory (Peters et al., 1998). The advent of fMRI studies of cognition and memory offers opportunities to take a new look at differences in encoding and retrieval of learned information across DID alter personality states.

Studies of individuals with high and low dissociative tendencies have revealed interesting differences in cognitive performance. Using DES scores, DePrince and Freyd (1999) divided undergraduates into high and low dissociative groups and administered selective and divided attention tasks using a version of the Stroop color naming test. This task requires the subject to name the color of ink that a word is printed in as rapidly as possible, but to ignore the word itself. Subjects were tested under two conditions. In the first, they named the color but ignored the words; in the second, they named the color and were told to memorize the words for later recall. The word list contained both neutral words and selected emotionally charged words. Following each condition, subjects were tested on their recall of words, although they had not been instructed to memorize the words in the first condition. Interference with the Stroop task was measured as the length of time required for the subject to accurately name the color of ink. High DES subjects showed more interference on the selective attention task (just naming the color) but performed better on the dual attention task (naming the color and memorizing the word). The researchers replicated these findings using a directed forgetting paradigm and new divided attention tasks. In the divided attention segment, the high DES subjects recalled fewer traumas but more neutral words than did the low DES subjects (DePrince & Freyd, 2001).

These studies, together with the Silberman et al. (1985) study, show that certain memory tasks can be constructed such that highly dissociative individuals perform better than control subjects. Memory tasks that involve division of attention or compartmentalization of highly similar information seem to favor highly dissociative individuals. Memory tasks that demand focused attention place them at a significant disadvantage. These attentional and memory

differences, perhaps together with other, as yet unrecognized cognitive differences, operating during critical periods of development and over the life span of the individual could lead to considerable deviation from normal developmental trajectories, as described in the section on the developmental model.

Psychophysiology of Dissociation

Reports of differences in handedness, visual ability, differential responses to various visual, tactile, olfactory, and auditory stimuli, and marked variations in energy level date back to some of the earliest case descriptions and by the nineteenth century became a staple of most case reports (Alvarado, 1989). Prince's GSR study begins a tradition of efforts at documentation using the most advanced technology of the time. By the 1950s, EEG became a favored measure, with famous cases such as Thigpen and Cleckley's (1957) *The Three Faces of Eve* and Ludwig's (Ludwig et al., 1972) Jonas demonstrating reported differences in mean alpha frequency across alter personality states. Today, these studies would be challenged for their uncontrolled designs and simple methodology. Recent, better-controlled studies, however, continue to find interesting differences. Measuring a battery of autonomic nervous system indices, including GSR, Zahn and colleagues (Zahn, Moraga, & Ray, 1996) found that 8 of 9 DID patients consistently manifested physiologically distinct personality states over several weeks. Three of the five simulating controls could, by using either hypnosis or deep relaxation, also manifest distinct "personality states," although these were significantly physiologically different from those produced by the DID patients.

J. J. B. Allen and Movius (2000) compared event-related potentials elicited by words learned in either the same or a different alter personality state for 4 DID patients. By this measure, they found little support for the existence of amnesia between personality states when compared with controls from another study who had deliberately concealed knowledge of previously learned words. Hopper et al. (2002) compared EEG coherence, a statistical estimate of the correlation between pairs of electrodes as a function of frequency, across the alter personality states of 5 DID patients and 5 simulating controls. The patients showed significant differences between personality states for alpha coherence in six brain regions; there were no differences for the controls. On average, the alpha coherence was higher in the host personality states than in the designated alter personality. EEG coherence is thought to be less sensitive to movement and muscle artifacts, which are potential confounds for prior EEG studies (Putnam, 1997).

The strategy of dividing traumatized subjects into high and low dissociative subgroups has also yielded interesting results for psychophysiological measures. Griffin and colleagues (1997) measured heart rate and skin conductance in 85 rape victims within 2 weeks of their rape. When asked to describe the rape, the high dissociative group reported the greatest subjective sense of distress, yet they decreased their heart rate and GSR arousal level relative to a neutral baseline. Other investigators are reporting similar findings in both child and adult samples. Using an index that includes both heart rate change and subjective distress, Bonanno and colleagues (2003) found that increased dissociation predicted a drop in heart rate together with an increased sense of distress for both sexually abused and control girls talking about a self-selected "most traumatic" life experience. This combination of increased distress and decreased heart rate predicted more PTSD symptoms, blunted emotion, and poorer outcome. Similar correlations between increased dissociation and decreased heart rate to stressors have been found in other studies (Koopman et al., 2004).

An inverse relationship between dissociation scores and urinary catecholamines has been reported by two studies. In 59 motor vehicle accident victims, peritraumatic dissociation was correlated with epinephrine but not norepinephrine in males, whereas females showed a reversed pattern of significance (Delahanty, Royer, Raimonde, & Spoonster, 2003). Simeon et al. (2003) found strong negative correlations between urinary norepinephrine and depersonalization scores in subjects with a *DSM-IV* diagnosis of Depersonalization Disorder. These results are congruent with the heart rate data, suggesting that high levels of dissociation act to suppress arousal in the face of stressors but do little or nothing to dampen subjective distress.

Neurobiology of Dissociation

Two primary sources of information inform our understanding of the neurobiology of dissociation. First, a body of case reports describes dissociative reactions in the context of illicit drug use or as a side effect of medications. Drugs that can precipitate dissociative-like reactions include alcohol, barbiturates and related hypnotics, benzodiazepines, scopolamine, β -adrenergic blockers, marijuana, other psychedelics, and anesthetics such as ketamine and its relatives. The number of different types of drugs producing dissociative-like reactions would suggest that many neurotransmitter systems could be involved in producing dissociative reactions.

A second source of information is the data from challenge studies using a range of “dissociative” drugs. Challenge studies with marijuana, infusions of lactate, yohimbine, mCPP, and ketamine elicit depersonalization in some subjects. These studies serve to narrow down the number of neurotransmitter systems likely to make significant contributions to dissociative states. The N-methyl-D-aspartate (NMDA) glutamate receptor, in particular, appears to play a central role in producing dissociative symptoms (Chambers et al., 1999).

Many of the drug challenge studies were conducted by John Krystal, Douglas Bremner, Steven Southwick, and colleagues (Bremner, Davis, Southwick, Krystal, & Charney, 1993; Bremner et al., 1995; Chambers et al., 1999; Charney, Deutch, Krystal, Southwick, & Davis, 1993; Krystal, Bennett, Bremner, Southwick, & Charney, 1995; Krystal et al., 1994) at the PTSD research center of the Yale-New Haven Veterans Administration Hospital. In a series of studies, they found that ketamine, an NMDA antagonist that increases glutamate release, produced dose-dependent increases in dissociation scores. In high doses, ketamine slows perception of time and produces tunnel vision, derealization, and depersonalization, similar to that described by trauma victims. Pretreatment with an anti-convulsant, either a benzodiazepine or lomotragine, which decreases glutamate release, reduces but does not entirely eliminate the dissociative effects of ketamine. Thus, dissociation, widely regarded as unresponsive to medication, may be susceptible to certain classes of drugs.

Krystal and colleagues (Chambers et al., 1999) propose the most comprehensive neurobiological theory of dissociation to date. This theory draws on preclinical data indicating that stress increases the release of glutamate and shows the similarity of the hyperglutamatergic effects of NMDA antagonists with stress- and trauma-induced dissociative symptoms. In summary, Krystal postulates that NMDA blockade decreases inhibitory tone, leading to increased glutamate release and consequently dissociative symptoms. This theory also accounts for the structural brain changes in the hippocampus found in MRI studies of PTSD subjects and controls. In two studies (DeBellis et al., 1999; Stein, Koverola, Hanna, Torchia, & McClarty, 1997), dissociation measures strongly correlated with volume loss in key brain regions implicated in PTSD.

Glutamate has a well-documented role in neuroplasticity, and increased glutamate release can lead to neurotoxic cellular events (De Bellis et al., 1999; Stein et al., 1997). Studies with marijuana and mCPP, however, implicate serotonin, and studies with yohimbine suggest that noradrenergic components may play roles in dissociation and PTSD symptoms, so additional systems beyond the NMDA

receptor system may be involved. Morgan and colleagues (2002), for example, found an important role for neuropeptide peptide Y (NPY) in dissociative responses to extreme stress. In two studies of military subjects undergoing high-stress training, they found a strong negative relationship between NPY levels and dissociative symptoms (Morgan et al., 2002). Thus, a number of candidate neurotransmitter systems have been identified that may contribute to dissociative symptoms individually and interactively.

THE CONTINUUM VERSUS THE TAXON MODEL OF PATHOLOGICAL DISSOCIATION

A century-old debate about whether dissociation occurs along a continuum proceeding from normal to pathological or represents a wholly different type of psychological organization has been resurrected by recent interest in the taxon model of dissociation. Janet (Putnam, 1989) advocated for a dissociative type, set apart from normal individuals. He believed that constitutional factors, suggestibility, and powerful emotional events contributed to the creation of a group of individuals who were fundamentally different from normal individuals. On the other hand, William James and Morton Prince (Putnam, 1989) argued for a continuum model, ranging from “normal” dissociative phenomena, such as absorption, to pathology, such as amnesias, fugues, and multiple personalities. Until recently, the continuum theory carried the day, although a few authorities cautioned about the possibility of a discontinuity of dissociative or trance phenomena. However, as data accrued across clinical and normal samples, it became apparent that there existed a distinct group of individuals who score high on dissociation measures irrespective of their psychiatric diagnosis. Different diagnostic groups contained different percentages of these high scorers, yielding different diagnostic group mean scores. The greater the percentage of high scorers, the greater the elevation of the group’s mean score relative to the group’s modal score. On the DES, for example, high scorers cluster around a mean score of 45, with the rest of the sample clustering around 8 (Putnam, Carlson, et al., 1996).

Based on these observations, a statistical study directly investigating the possibility of a dissociative “type” of individual was undertaken. Using newly developed taxometric approaches, Waller et al. (1996) examined item-response data for manifestations of a latent class variable. Eight DES items, composing the DES-T subscale, could robustly differentiate Dissociative Disorder patients from other psychiatric patients and normal controls. Indeed, the normal controls almost never endorsed these eight items. Subsequent studies confirm that a taxonic approach is a clinically useful way to

identify a distinct subgroup of dissociative patients within any given diagnosis. These high dissociative individuals will differ on important symptoms and features from the rest of the diagnostic group (J. G. Allen, Fultz, Huntoon, & Brethour, 2002; Seedat et al., 2003; Waller, Ohanian, Meyer, Everill, & Rouse, 2001). Dividing subjects into high and low scorers has proven fruitful for identifying distinctly different physiological and cognitive responses to stimuli that serve as traumatic reminders.

Implications of the Taxon Model

A taxonic model of dissociation would imply a significantly different developmental trajectory than the continuum model. It would also require a different approach to treatment, that is, changing a type rather than lowering an elevated level of dissociation. The typological differences between high dissociators and others either could be the result of a strong genetic predisposition or could arise from a fundamentally different early developmental trajectory. A convincing genetic difference remains to be demonstrated, but research linking dissociation with Type D attachment disturbances offers a potential mechanism for the latter.

The continuum model of dissociation conceptualizes a positive treatment response as moving the individual back toward the “normal” segment of the dissociation continuum. In a taxonic model, a positive treatment outcome implies shifting the individual’s type from the dissociative to the nondissociative type. Treatment outcomes such as fusion or integration into a unified personality of the DID alter personalities suggests this possibility (Kluft, 1984b). Beyond these clinical accounts, however, no empirical data exist to confirm that integration clinically produces a taxonic change. To date, the few treatment outcome studies of DID patients including pre- and posttreatment dissociation measures show moderate (but significant) decreases in scale scores rather than a significant taxonic shift from the dissociative to nondissociative categories (Choe & Kluft, 1995; Coons, 1986; Kluft, 1988; Ross, 1989). The taxonic model has proven valuable in spurring researchers to compare high and low dissociators on a variety of measures. The clinical utility of the taxon as an index of therapeutic success remains to be tested.

CHILD AND ADOLESCENT DISSOCIATION

In the 1970s, pioneers with child cases such as Cornelia Wilbur and Richard Kluft sparked modern interest in dissociative disorders in children and adolescents (Kluft, 1984a; Putnam, 1997). In particular, Wilbur’s recognition

of the role played by child abuse in DID was instrumental in focusing attention on the effects of early trauma on child development. Long forgotten case reports, in which nineteenth-century clinicians sometimes used Latin phrases to mask their suspicions of incest, were subsequently rediscovered. Small case series and reviews of childhood dissociative disorders began appearing by the mid-1980s, with ever more systematic studies appearing in the past decade. In modern cases, significant early trauma is a common feature.

Diagnosis

For the most part, the core phenomenology of child and adolescent dissociative disorders is similar to corresponding adult dissociative symptoms (Hornstein & Putnam, 1992). The day-to-day manifestation of the dissociative symptoms does vary with the child’s age, as is the case for childhood manifestations of virtually all lifelong psychiatric disorders. Older children and adolescents, in general, are more overtly symptomatic than younger children. This may reflect, in part, the ability of older children to better report subjective distress as well as their greater opportunity to manifest their psychopathology in ways that bring attention to their problems.

Putnam, Hornstein, et al. (1996) found that amnesias, identity disturbances, and auditory hallucinations increased with age in a pooled sample of 177 child and adolescent dissociative disorder cases. Trance-like and spaced-out behavior, however, were ubiquitous across all age groups. Comorbid pathology such as suicidal ideation, self-mutilation, and somatization increased with age in parallel with dissociative symptoms. Children and adolescents with DID were the most symptomatic across all age groups. This is congruent with the belief that DID is the most severe of the dissociative disorders.

Males and females did not differ on dissociative symptoms, but females were significantly more symptomatic for anxiety and phobic symptoms, PTSD, sleep disturbances, sexual acting-out, and somatization. These findings closely parallel the gender differences in adult clinical profiles. The other significant finding was the steady increase in the ratio of female to male cases reported for each age group (Putnam, Hornstein, et al., 1996). By late adolescence, approximately 80% of the cases in the sample were female (Figure 18.1, “Age”), which duplicates the percentages of females reported in many adult samples (Putnam, 1997).

The most extensive examination of the clinical phenomenology of formally diagnosed child and adolescent dissociative disorders is a sample of 64 cases collected at two separate sites. Using a standard case collection protocol,

Figure 18.1 Increasing ratio of female to male dissociative disorder diagnoses by age. *Source:* From “Clinical Phenomenology of Child and Adolescent Dissociative Disorders: Gender and Age Effects,” by F. W. Putnam, N. L. Hornstein, & G. Peterson, 1996, *Child and Adolescent Psychiatric Clinics of North America*, 5(2), pp. 351–360.

Hornstein and Putnam (1992) first compared the two case series on 16 clinical factors, abuse histories, and CDC scores. Finding no differences, they combined the two samples and enumerated the clinical profiles. There were significant differences between cases diagnosed as DID versus DDNOS. On every measure, the DID cases were more symptomatic, with most differences reaching Bonferroni-corrected levels of significance. Dissociative Identity Disorder patients were significantly older than DDNOS patients. The average child in the sample had received 2.7 (± 1.3) prior diagnoses, the most common being Major Depression (45.3%) and PTSD (29.6%). Affective and anxiety symptoms were prominent in many clinical presentations, and suicidal ideation was common in both groups, with DID cases making significantly more attempts. Rapid mood swings and marked irritability were almost universally reported for all cases.

The most common dissociative symptom was frequent episodes of amnesia reported by and observed in these children. Dissociative Identity Disorder cases had more total amnesias and more amnesias that could not be directly related to traumatic precipitants or reminders. Dissociative Identity Disorder patients had significantly more passive influence experiences (made thoughts and feelings, involuntary motor activity, automatic writing, etc.). Dissociative Identity Disorder cases also had more auditory hallucinations, particularly command hallucinations, urging the child to commit aggressive or self-harm acts. Both DID and DDNOS groups exhibited rapid age regression

phenomena and rapid shifts in demeanor or personality characteristics. Trance-like behavior was ubiquitous.

A comparison of child and adolescent presentations, irrespective of dissociative diagnosis, revealed that adolescents were more symptomatic across the board, although not all comparisons of symptoms reached Bonferroni-corrected statistical significance. Significantly more (>95%) adolescent cases met criteria for DID. It should be noted, however, that the determination of symptoms and the verification of a diagnosis of DID by meeting one or more alter personality states is easier in adolescents.

As is apparent from the Hornstein and Putnam (1992) study, DID is often not formally diagnosable until mid- to late adolescence, although pathological dissociative precursors may be apparent in younger children. Clinicians sometimes refer to such cases as “incipient multiple personality” or “multiple personality in evolution.” Peterson and Putnam (1994) proposed an alternative diagnosis of Dissociative Disorder of Childhood (DDoC) to characterize children who were showing significant dissociative psychopathology but who did not have fully crystallized alter personalities. This diagnosis called attention to the pathological dissociation while seeking to avoid the stigma, controversy, and unwelcome attention often associated with a diagnosis of DID. They tested a set of diagnostic criteria by surveying therapists treating children and adolescents carrying a dissociative diagnosis. The four-part diagnostic criteria required (1) 6 months or more of a significant behavioral disturbance characterized by amnesia or trance-like states; (2) perplexing fluctuations in behavior or preferences; (3) at least three dissociative process symptoms (internal auditory hallucinations, vivid imaginary companionship, third-person self-references); and (4) that the patient did not meet criteria for DID. Cases meeting DDoC criteria were distinguishable on clinician report measures such as the Child Dissociative Checklist from patients meeting *DSM* criteria for DID and from a second group with few dissociative symptoms. Although this proposed diagnosis was not adopted in *DSM-IV*, efforts continue to refine diagnostic criteria for a more developmentally sensitive Dissociative Disorder.

Dissociation and the Development of Psychopathology

A second developmental look at the interactions of childhood trauma, family environment, dissociation, and psychopathology emerges from studies with dissociation scales. Validated child and/or adolescent dissociation measures have been administered to a variety of clinical and nonclinical samples (Brunner et al., 2000; Calamari & Pini,

2003; Carrion & Steiner, 2000; Farrington et al., 2002; Kisiel & Lyons, 2001; Macfie, Cicchetti, & Toth, 2001a; Prohl, Resch, Parzer, & Brunner, 2001). Scores were significantly higher for traumatized (typically physically abused) versus nontraumatized subjects across all age groups. Higher levels of dissociation were also significantly associated with more general psychopathology. Among maltreated preschoolers, Macfie, Cicchetti, and Toth (2001b) found robust correlations with externalizing and internalizing behavior problems for both boys and girls. A comparison of these maltreated preschoolers with demographically and family constellation-matched, nontraumatized preschoolers found that the maltreatment group had significantly increased levels of dissociation a year later, with the physically abused children accounting for the greatest increase in scores. The controls showed substantial decreases in their dissociation scores over the same period, in line with the often reported decrease in dissociation scores with age in normal children.

DEVELOPMENTAL PRECURSORS AND SUBSTRATES OF PATHOLOGICAL DISSOCIATION

Imaginary Companionship

Clinicians working with childhood DID initially focused on childhood imagination phenomena such as imaginary companionship as likely developmental precursors for dissociative disorders. Depending on the age of the child and the definition used, imaginary companions are reported in 20% to 60% of normal children (Taylor, 1999). Widely regarded as benign, normal imaginary companionship is commonly considered to be a sign of creativity in young children. It does become increasingly suspect, however, in older children and adolescents and is generally considered to be a sign of psychopathology in adults. The rates of imaginary companionship in child dissociative cases range from 42% to 84%, with the highest rates reported for children diagnosed with DID (Putnam, 1997). It should be noted, however, that the rates reported in DID case series overlap with the range reported in studies of normal children. Thus, although imaginary companionship may be a developmental substrate that is reshaped by early trauma for psychological defensive purposes, it is not pathognomic for pathological dissociation.

The best clinical study, by Trujillo, Lewis, Yeager, and Gidlow (1996), found imaginary companions in 57% of a residential treatment sample of maltreated boys compared to 30% of a normal comparison group of schoolchildren.

The imaginary companions in the clinical sample differed, however, in significant ways from the normal boys' imaginary companions. Maltreated boys averaged 6.4 entities compared with 2.5 imaginary companions in the normal boys. The imaginary companions of the normal boys were benign and benevolent, often with endearing names like "Thumper" and "Boom-Boom." They were typically voluntarily elicited, primarily as playmates. Most appeared between ages 2 and 4 years, and all had disappeared by age 8 years. In contrast, the imaginary companions described by the boys in residential treatment served other functions, including (1) helpers and comforters, (2) powerful protectors, and (3) family members. The imaginary companions of the residential boys were still present at a mean age of 10.6 years, well after they had disappeared in the normal boys. The imaginary companions of the maltreated boys often had names such as "God," "The Devil," and "Guardian Angel." Clinicians should be aware of the possibility that children who report talking with God or the Devil may actually be referring to their imaginary companion and not expressing more abstract religious beliefs. Clinicians experienced with DID cases theorize that at least some of the imaginary companions found in maltreated children eventually evolve into the alter personality states that characterize DID. As yet, no one has documented this transformation; however, autobiographical accounts of DID patients do sometimes report that this happened with them.

Type D Attachment

In the context of seeking to code attachment with disturbed mother-infant pairs, Main and Solomon (1986) identified a new pattern of attachment: insecure-disorganized/disoriented or Type D attachment (Hesse & Main, 2000; Main & Solomon, 1986). Type D attachment is defined by a characteristic set of behaviors in the standard Strange Situation (Ainsworth, Blehar, Waters, & Wall, 1978): (1) the complete absence of an apparent attachment strategy; (2) contradictory behaviors or affects occurring virtually simultaneously; (3) freezing, stilling, apparent dissociation; (4) abnormal movements; or (5) direct indices of apprehension of the parent (Green & Goldwyn, 2002). The wide range of behaviors included under this classification makes it apparent that Type D samples are behaviorally heterogeneous. The base rate for Type D attachments in low-risk families is approximately 15% but rises much higher in certain samples (van Ijzendoorn, Schuengel, & Bakermans-Kranenburg, 1999).

Main and Hesse (1990) theorized that Type D attachment arose as a result of the child simultaneously

experiencing the parent as both frightening and necessary for survival. They characterized the caregiver behavior as being frightening and/or frightened (Main & Hesse, 1990). Research has now convincingly linked parental factors, especially unresolved parental loss or trauma, in the development of Type D attachment in children (Schuengel, Bakermans-Kranenburg, & van Ijzendoorn, 1999). Not surprisingly, the highest rates of Type D attachment occur in samples of maltreated infants and toddlers. For example, V. Carlson, Cicchetti, Barnett, and Braunwald (1989) found that 82% of a maltreated group of 12-month-olds were classified as Type D compared with 19% of a demographically matched, welfare-dependent sample. They also found that more maltreated boys than girls qualified as Type D. Following a maltreatment sample and matched controls for 1 year, Barnett, Ganiban, and Cicchetti (1999) found that Type D classifications were stable and predictive of negativity in the child.

Children classified as Type D or disorganized have poorer outcomes across many domains (Green & Goldwyn, 2002). These include lower academic attainment, lower self-esteem, poor peer interactions, unusual or bizarre classroom behaviors, cognitive immaturity, and externalizing behavior problems (Green & Goldwyn, 2002; Lyons-Ruth, Alpern, & Repacholi, 1993). Studies have also found that Type D children show significantly greater hypothalamic-pituitary-adrenal (HPA) axis reactivity to stressors (Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Schuengel et al., 1999). Salivary cortisol collected after a Strange Situation did not differ among infants classified as having A, B, or C attachment patterns but was significantly higher in Type D infants (Hertsgaard et al., 1995). Given that the Strange Situation is considered to be a mild stressor, it is likely that many of their life experiences evoke even stronger HPA axis responses.

Type D Attachment and Dissociation

In 1992, Giovanni Liotti extended a line of theory, first proposed by Peter Barach (1991), that dissociation is etiologically related to disturbances in parent-child attachment, specifically Type D attachment disorder (Liotti, 1992). He hypothesized that “the infant’s disorganized/disoriented attachment behavior . . . correspond[s] to the construction of an internal working model of self and the attachment figure that is multiple and incoherent” (Liotti, 1992, p. 199). He further speculated that the severity of the dissociative outcome of Type D attachment patterns would depend on subsequent life experiences, especially on the degree of exposure to frightening and nonfrightening caretakers or traumatic experiences.

Indeed, subsequent research finds converging evidence for a linkage between pathological dissociation and Type D attachment patterns. Two separate analyses of data from the prospective, longitudinal Minnesota Mother-Child Project study found that attachment disorganization in infancy predicted increased dissociation in adolescence (E. A. Carlson, 1998; Ogawa, Sroufe, Weinfield, Carlson, & Egeland, 1997). In a sample of 168 young adults, Ogawa et al. found that three variables measured in infancy accounted for 30% of the variance in DES scores at age 18 to 19 years: (1) attention span subscale of the Carey (negative β), (2) maternal psychological unavailability, and (3) a disorganized pattern in the Strange Situation. Using a structural equation modeling approach with an overlapping sample of 157 subjects, E. A. Carlson likewise found that early caregiving mediated disorganized attachment, which, in turn, mediated dissociation, accounting for 15% of the variance in DES-T scores at age 19.

In further support of this hypothesis, Main and Morgan (1996) found that a mother’s DES score was a good predictor of her infant’s disorganized behavior. Examining the nature of parent-child interactions with parents of Type D infants, Hesse and Main (2000) described many dissociative-like behaviors, including alternations among multiple discrete behavioral states that trigger disorganized behaviors in their infants. Thus, one can begin to posit a transgenerational dynamic in which increased maternal dissociation contributes to disorganized attachment, which, in turn, contributes to increased dissociation in adulthood, including parenting behaviors—and on through successive generations when other factors (e.g., trauma and adversity) co-occur.

Developmental Mediation of Psychopathology by Dissociation

Several studies have examined whether dissociation mediates the relationship between trauma and one or more types of psychopathology. The standard statistical approaches to determining mediation involve three variables: (1) the predictor variable: in this case, some form of trauma; (2) the putative mediating variable: dissociation; and (3) the outcome. All three variables must be intercorrelated. Mediating effects are tested by partialling out the contribution of the putative mediating variable, either through multiple regression or an analysis of covariance (Baron & Kenny, 1986). If there is a mediation effect, the strength of the relationship between the predictor variable and the outcome variable will be significantly reduced or eliminated.

In clinical samples of adult women with histories of abuse, dissociation mediated a range of symptoms, including anxiety, compulsions, depression, phobias, and ruminations (Becker-Lausen, Sanders, & Chinsky, 1995; Ross-Gower, Waller, Tyson, & Elliott, 1998). Kisiel and Lyons (2001) explored the possible mediating role of dissociation in the development of psychopathology in sexually abused children and adolescents. Measuring psychopathology with a variety of standard measures, they found that the main effect of sexual abuse on behavioral problems disappeared when they controlled for levels of dissociation as measured either by a self-report measure (A-ADES) or by observer report (CDC). This is a well-accepted statistical test of a putative mediating variable. These data are congruent with similar studies showing dissociation as mediating psychopathology in adults (Lyubomirsky, Casper, & Soursa, 2001; Offen et al., 2003; Ross-Gower et al., 1998; Somer, 2002). A path analysis study of 156 sexually abused children found three direct pathways to PTSD symptoms, of which dissociation was by far the strongest contributor (Kaplow, Dodge, Amaya-Jackson, & Saxe, 2005). The authors concluded that children who reported dissociative symptoms immediately after disclosure of abuse were at greatest risk for subsequent PTSD. They theorized that the dissociative symptoms may have interfered with the processing of traumatic effects and memories and increased reexperiencing symptoms.

Psychopathological Mechanisms

The possibility that dissociation is a critical mediating variable for subsequent psychopathology has significant implications for early intervention with maltreated and traumatized children. Assessment of dissociation should be a standard part of the evaluation of traumatized children and adolescents, and significant elevations should be addressed as part of the treatment plan. The mechanism(s) through which dissociation mediates the development of psychopathology remains to be established. It is theorized that dissociative effects on memory, coherence of self, and self-agency play a significant role in undermining the development of a healthy sense of self and appropriate socialization (Putnam, 1997). The negative effects of high levels of dissociation on child development are postulated to operate through impacts on elaboration of a sense of self, acquisition of emotional regulation, impulse control, impairments in information processing, and psychophysiological responses to stressors. Each of these developmental threads interacts with others to shape the child's emerging capacities in ways that may lead to profound differences in

psychological organization compared to individuals with low levels of dissociation.

Children elaborate, assemble, and seek to integrate a complex, multidimensional sense of self over the course of development. Dissociative symptoms such as autobiographical amnesias, depersonalization, and passive influence experiences interfere with the integration of self and the development of a unified sense of self-agency. In a study of outcomes of Israeli rape and domestic violence victims and controls, dissociation mediated much of the variance between trauma and emotional distress (Somer, 2002). Dissociation also indirectly mediated increased introspectiveness, which accounted for part of the trauma-emotional distress relationship. Introspectiveness has been associated with developmental discontinuities, which are theorized to stimulate intensive reappraisal of the self.

Dissociative amnesias that interrupt the continuity of experience disrupt a child's understanding of cause-and-effect sequences. Antecedent negative or risky behaviors do not seem to be connected to their subsequent consequences; thus, consequences of prior actions are experienced as coming from out of the blue. These "expectable" consequences, then, are not associated with the behaviors that caused them. As a result, dissociative children have a great deal of difficulty learning from experience (Putnam, 1997). Dissociative symptoms such as depersonalization disrupt the metacognitive function of self-monitoring behavior. In turn, this is believed to interfere with the integration of a sense of self across contexts, thus further complicating the child's ability to learn and practice self-control, particularly in the context of stressors. Dissociation is well-correlated in numerous studies with increased aggression, impulsivity, and poorer social skills (Brunner et al., 2000; Carrion & Steiner, 2000; Kisiel & Lyons, 2001; Macfie et al., 2001a, 2001b; Putnam, 1997; Walker, 2002; Zoroglu et al., 2003).

Chronic depersonalization, believed to be related to the emotional numbing seen in PTSD patients, is theorized to promote a sense of detachment from self that fosters risky and self-destructive behavior, including self-mutilation. Increased dissociation is highly correlated with increased self-mutilation in numerous studies (Paul, Schroeter, Dahme, & Nutzinger, 2002; Saxe, Chawla, & van der Kolk, 2002; Zoroglu et al., 2003). Self-inflicting pain is often described by dissociative patients as an attempt to break through profound states of depersonalization. At other times, however, they describe feeling no pain when they cut or burn themselves. This sense of alienation from self is also believed to contribute to the high rate of suicide attempts in dissociative patients. Dissociation has been

implicated in predisposing an individual to revictimization (Noll et al., 2003); whether this represents a form of self-harm, a lack of investment in self, or a failure of vigilance remains to be determined. In total, these experiences increase an individual's risk for further traumatization, which takes a cumulative toll on the individual's life.

Studies with high and low dissociators have established significant cognitive differences for certain attentional tasks. The full range of these cognitive differences remains to be elucidated, but it is postulated that they alter the dissociative child's ability to process information in normative ways. Prospectively comparing sexually abused girls with carefully matched controls, Trickett, McBride-Chang, and Putnam (1994) found that dissociation was negatively associated with competent learning and overall classroom performance and strongly predictive of school avoidance. The combination of cognitive dysfunctions and negative school trajectories puts dissociative children at an academic disadvantage, which has profound implications for adult attainment. Other, longer-term social effects, such as cross-generational impact on the quality of parenting and thus attachment with one's own children, are also likely. For example, a cross-sectional study of college students found dissociation to be a mediator between child abuse histories and scores on a measure of child abuse potential (Narang & Contreras, 2000). Thus, as many have speculated clinically, increased dissociation may increase risk for poor parenting and thus perpetuation of child maltreatment into another generation.

Protective Factors

The military stress studies by Morgan and colleagues (2002) suggest that some factors must help to protect individuals against developing dissociation under severe stress. The major biological finding to date is that levels of neuropeptide-Y secreted during stress are inversely related to dissociative symptoms and positively related to superior performance (Morgan et al., 2002). The longitudinal Minnesota Mother-Child Project found that in high-risk children, dissociation at Time 5 was negatively correlated with Time 2 measures of self-esteem and ego resilience for children subsequently traumatized at Times 3 and 4. Thus, a more developed and healthier sense of self at an early age appeared to act as a protective factor against dissociation from later trauma (Ogawa et al., 1997). There are probably other protective factors operating that have yet to be elucidated.

The influence of genetic factors remains unclear. The two twin studies to date report contradictory findings, with one attributing a significant amount of the variance to genetic

factors and the other finding only a significant relationship with shared environment. Identification of environmental protective factors may help stimulate intervention models that prevent the development of significant dissociation in acutely traumatized children.

In summary, the developmental model of pathological dissociation postulates that childhood trauma-related dissociation may be mediated in part through its effects on attachment, especially Type D disturbances of attachment. Attachment is a basic social/biological process that fundamentally impacts the development of self and socialization. Much of the comorbid psychopathology common in Dissociative Disorder patients and in psychiatric patients with high levels of dissociation are believed to be associated with early disturbances of attachment with a primary caretaker. The developmental model of dissociation is consistent with the taxonic model of dissociation that postulates that individuals with dissociative disorders differ in a fundamental way from others, as opposed to simply being further along on a continuum of dissociation. The taxonic model implies that the dissociative individual must travel a very different developmental trajectory, particularly with respect to the integration of self, over childhood and adolescence than do nondissociative individuals. A fundamental disturbance of attachment, as represented by the Type D classification, could set the stage for the elaboration of dissociation, which, in turn, may mediate the development of the associated comorbidity commonly seen in such cases.

Treatment of Dissociation in Children and Adolescents

Dissociative Children

A discussion of the current state of the art of treatment for dissociative children and adolescents needs to differentiate between children with discernable dissociative symptoms and behaviors but without a diagnosable dissociative disorder and those who meet formal *DSM* criteria. The former are relatively common, but the latter are relatively rare. The inclusion of child and adolescent scales and measures in numerous studies has documented high levels of dissociation in clinical samples of children and adolescents with a number of disorders (Brunner et al., 2000; Calamari & Pini, 2003; Keck-Seeley, Perosa, & Perosa, 2004; Prohl et al., 2001; Sanders & Becker-Lausen, 1995; Sanders & Giolas, 1991; Yoshizumi, Murase, Honjo, Kaneko, & Murakami, 2004; Zoroglu, Sar, Tuzun, Tutkun, & Savas, 2002). Elevated dissociation is also common in adolescents in the juvenile justice system and among runaways (Brosky

& Lally, 2004; Friedrich et al., 2001; Koopman et al., 2004; Plattner et al., 2003; Tyler, Cauce, & Whitbeck, 2004).

Eating disorders have been among the best documented disorders associated with increased dissociation in adolescents (Farrington et al., 2002; Gleaves & Eberenz, 1995; Hartt & Waller, 2002; Rosen & Petty, 1994; Valdiserri & Kihlstrom, 1995). Although most reports link disordered eating with increased dissociation, there is no clear pattern differentiating anorectic from bulimic patients. Eating disorder patients scoring high on dissociation measures are, however, generally more symptomatic and more refractory to treatment than low-scoring patients. In some studies, the magnitude of the dissociation effect, though significant, does not account for much of the variance. Where childhood trauma, especially sexual abuse, has been concurrently assessed, it is more highly correlated with the dissociation than with measures of disordered eating. This suggests that dissociation is probably not a major mediator of disordered eating but is more likely related to the high incidence of sexual abuse reported by many eating disorder studies.

Self-mutilation and self-destructive behaviors seem to be more directly related to increased dissociation in a subset of troubled adolescents (Gratz, Conrad, & Roemer, 2002; Matsumoto, Azekawa, Yamaguchi, Asami, & Iseki, 2004; Noll et al., 2003; Turell & Armsworth, 2000; Yates, 2004; Zoroglu et al., 2003; Zweig-Frank, Paris, & Guzder, 1994). In some instances, the self-destructive behavior occurs during a dissociative state; in other instances, it seems to be an attempt by the individual to break out of a painful state of depersonalization/derealization. In a number of instances, individuals have committed murder while in a dissociative state (Ferracuti & DeMarco, 2004; Spinelli, 2001). Spinelli's investigation of multiple cases of neonaticide found a common pattern of a denial of the pregnancy, followed by depersonalization, dissociative hallucinations, and intermittent amnesia during delivery.

In aggregate, these reports indicate that dissociation should be routinely assessed in troubled children and adolescents, particularly if they have histories of self-destructive or assaultive behavior. Currently, there are no systematic data on responsiveness of dissociative symptoms and behaviors in children or adolescents who meet criteria for another disorder. Unpublished data indicate that dissociation, as measured by the CDC, declines in traumatized preschoolers treated in a therapeutic preschool program (J. Sites, personal communication, November 2004). This decline in dissociation scores over a 1-year period was accompanied by marked improvements across a broad range of social and academic measures, although a causal relationship was not demonstrated. Similar, and as

yet anecdotal, results among young children have been described by others but remain to be fully documented. The improvement in many of these cases was not associated with treatment directed at the dissociation, but rather the creation of safe, stable, supportive, and structured environments with clear expectations and contingencies. This is congruent with some recommendations for treatment of dissociative disorders in young children (Putnam, 1997).

Children with Dissociative Disorders

A set of guidelines for the treatment of dissociative disorders in children and adolescents has been published by a task force of the International Society for the Study of Dissociation (ISSD; Silberg, 2000b). These guidelines provide a general framework from which to approach the treatment of highly dissociative children and adolescents. The first step is an assessment, including a complete history of the child and the child's caretaking environment. The clinical interview should include questions about imaginary friends, auditory and visual hallucinations, perplexing forgetfulness, numbing, anxiety, nightmares, self-injury, flashbacks, somatic concerns, depersonalization and derealization, and identity alteration or confusion. In addition, measures such as the CDC or A-ADES are recommended. Formal psychological testing, including documentation of the signs and behaviors noted by Silberg (1996a), may be indicated if resources are available. Given the significant comorbidity that often accompanies pathological dissociation, the evaluation should also assess for Obsessive-Compulsive Disorder, PTSD, Reactive Attachment Disorder, Attention-Deficit/Hyperactivity Disorder, affective disorders, substance abuse, and developmental disorders. A thorough physical examination may well be indicated. Conditions such as epilepsy, narcolepsy, and other neurological disorders should be considered in the differential diagnosis (Putnam, 1997).

The creation of true safety for the child, both physical and psychological, is a necessary prerequisite to successful treatment (Putnam, 1997; Silberg, 2000b). Once safety has been ensured, the role of the therapist is to create a stable sense of continuity and structure for the dissociative child, both in terms of the therapist's interactions and in the child's larger milieu. Often, this requires working with caretakers, teachers, and others important in the child's daily life (Putnam, 1997). A team approach is best but, as always, requires active and ongoing efforts to coordinate care and to ensure the continuity of cause and effect, stimulus and response that is critical to cutting across the dissociative compartmentalization of knowledge and behavior that fragments the child's experience of the world. This

must be balanced against the issues of confidentiality that become increasingly important with adolescents.

The ISSD guidelines list a series of therapeutic goals (Silberg, 2000b). Foremost among these is helping the child acquire a sense of cohesiveness and continuity of self and behavior. The effort is to help children become aware of their behavior and its relationship to prior experience, current stressors, and subsequent consequences. The therapist must help the child accept responsibility and exert control over his or her actions. As with PTSD, dissociative disorders sap motivation and the hope that things can improve. The therapist should help the child identify strengths and motivate the child to explore possibilities for change. Internal conflicts, often personified as pejorative auditory hallucinations or dueling alter personalities, need to be identified and articulated. Depending on the child's age, various therapeutic modalities can be used to work through these issues, including play therapy, art therapy, journaling, and video narratives.

The core of treatment for most dissociative disorders, as with PTSD, is the processing of traumatic memories. This is made more difficult by the amnesias for traumatic experiences and dissociative responses to threatening and anxiety-provoking material. Discussions of various approaches to therapeutic processing of traumatic material with children and adolescents are detailed in volumes devoted to treating dissociative children and adolescents (Putnam, 1997; Silberg, 1996a). Promotion of autonomy and the self-regulation of affective state are also important treatment goals. Helping dissociative children identify traumatic triggers and stimuli that elicit changes in emotional state should occur both in therapy and in the milieu. Cognitive-behavioral and anxiety-reduction techniques are tools to help children and adolescents gain mastery over their dissociative and traumatic reactions to stressors.

Finally, the promotion of healthy relationships is aimed at the disrupted attachments that these children experienced in the context of maltreatment and other traumas. Helping these children to express their feelings, fears, and compulsions rather than acting on them is an ongoing task for the therapist, caretakers, and important others in the child's environment. It often falls to the therapist to work with foster parents, teachers, residential treatment staff, and others to help them to maintain appropriate boundaries and the continuity of their relationships with the child in the face of acting-out behavior. The maintenance of stable, predictable, reasonable responses to provocative and dissociative behavior by the child helps to promote healthy relationships.

Treatment of children and adolescents with dissociative disorders generally occurs simultaneously in a series of arenas, including individual, family, and educational settings. Inpatient and/or residential treatment may also occur during the course of treatment. Beyond the clinical reports and anecdotal accounts, little is known about the outcomes of these interventions. Overall, the literature has been optimistic for children (Putnam, 1997; Silberg, 1996a, 2000a). There appears to be somewhat less success with adolescents (Dell & Eisenhower, 1990; Putnam, 1997). Randomized clinical trial studies now demonstrate the efficacy of cognitive-behavioral treatments for sexually abused children with PTSD symptoms in general (Cohen, Deblinger, Mannarino, & Steer, 2004). These approaches should be extended to research with children with high levels of dissociation and dissociative disorders.

SUMMARY AND FUTURE DIRECTIONS

This chapter provided a comprehensive and synthetic overview of the relevant features of dissociation and the dissociative disorders as they pertain to the development of psychopathology. Dissociation is a remarkably global process that appears to influence the expression of a wide range of critical psychological and biological capacities in ways that lead to fundamental differences in some individuals' subjective experience of self and others.

Historically, dissociative individuals have been clinical and public curiosities who generated fascination and skepticism in turn. Yet, the early study of these conditions was instrumental in the recognition of unconscious mental processes and the emergence of psychodynamic psychology and psychiatry. This fascination also led to the elaboration of misleading stereotypes, particularly for Multiple Personality Disorder, that continue to plague the field and obscure the importance of dissociation as a fundamental mental process capable of leaving a profound stamp on the development of an individual. Modern perspectives on dissociation, increasingly informed by experimental data, are gradually shedding this historical baggage and replacing prior fascination with a more calibrated understanding of the effects of dissociation on memory, cognition, biology, and behavior.

The measurement of dissociation by reliable and valid scales and diagnostic interviews has revolutionized our understanding of both the fundamental process and the disorders that arise from pathological levels of dissociation. Similar to the change in our understanding that occurred

for depression and anxiety, the ability to simply and meaningfully quantify dissociation has resulted in hundreds of peer-reviewed publications including dissociation among the constructs measured for a wide range of clinical and population samples. The results have better elucidated the relationship of dissociation to etiological factors as well as its relationship to a range of comorbid psychopathology.

Increasingly sophisticated statistical approaches are extracting latent information embedded in the distributions of dissociation scores. The preliminary results suggest the possible existence of a latent dissociative type or taxon that may mark a different psychological organization with respect to the integration of self and behavior. Although this remains to be proven, the broader recognition that high levels of dissociation seem to lead to qualitatively different types of responses to standard stimuli has led to laboratory experiments in which subjects are divided into high and low dissociative groups. Cognitive experimental tasks can be devised such that high dissociative individuals perform significantly better than normal individuals. Likewise, experimental tasks can be constructed in which high dissociative individuals perform more poorly than normal controls. In these experiments, the critical difference between the two tasks is the subject's focus of attention, with dissociative subjects performing poorly on selective attention tasks but superiorly on dual attention tasks. A similar high-low division strategy with clinical samples such as rape victims has demonstrated that highly dissociative individuals manifest significantly different physiological responses to experimental stimuli that are reminiscent of the original trauma. In this case, they typically show a decrease in sympathetic arousal in the face of stressors, while nonetheless experiencing significant subjective distress. Future research should both expand our understanding of the range of cognitive and physiological differences associated with high levels of dissociation and further elucidate their underlying neurobiological mechanisms.

Dissociation scales such as the DES and PDEQ were central to the documentation that antecedent traumatic experiences are highly related to increased levels of dissociation, both acutely and chronically. The set of cognitive and psychophysiological responses to experimental stimuli exhibited by high dissociative patients can be profitably compared with low dissociative subjects with and without PTSD. These and other contrasts will be important in better characterizing the range of human responses to trauma of all kinds. Comparison of high and low dissociative subjects on various indices of trauma severity as well as age/developmental stage and other factors should help

identify some of the missing variance in our understanding of what makes a given experience traumatic.

Incorporation of dissociation measures into longitudinal studies will permit us to follow its operation across development and identify susceptible periods that may also represent opportunities for intervention. Within a given diagnostic group, for example, Borderline Personality Disorder or Somatization Disorder, dividing subjects into high and low dissociative groups may yield critical evidence about responses to treatment and help to clarify why certain patients fail to improve with standard therapies. A baseline evaluation with follow-up monitoring of dissociation over the course of treatment may provide an important marker of clinical improvement or deterioration for clinicians. Experimental studies with dissociogenic drugs such as ketamine point to pharmacologically responsive neurobiological substrates that may ultimately prove to be targets for antidissociative medications. We have reached a stage in our understanding of dissociation when we can test more systematic approaches to treatment than the roughly staged psychodynamic psychotherapy that is the current mainstay.

Developmentally, the discovery that attachment disorders, especially Type D attachment, predict long-term dissociation levels has opened up a fertile area of scientific investigation. The strong relationship between Type D attachment and maltreatment, in turn, completes a loop linking the two factors that predict the most variance in long-term levels of dissociation. Much remains to be sorted out here in terms of developmental sequences and a myriad of interactions with other variables, but, unlike many other psychiatric conditions, in the case of dissociation there is a strong early developmental marker, Type D attachment, that can be traced forward. Current child and adolescent dissociation measures are sufficiently psychometrically sound and concordant to allow us to confidently follow dissociative trajectories in long-term longitudinal studies and assess their contribution to a range of psychopathology.

The preliminary results indicating that dissociation acts as an important mediating factor for the transduction of traumatic experience into maladaptive symptoms and behavior are congruent with a wide array of cross-sectional studies linking elevated levels of dissociation to broadly increased psychopathology in clinical and non-clinical samples. Dissociation is most strongly correlated with externalizing behavior problems, sexual behavioral problems, and somatization in children. Many studies demonstrate that increased externalizing behavioral problems are associated with deviant life trajectories and negative outcomes. By adolescence, revictimization and

self-harmful behaviors become increasingly linked to dissociation, indicating its deleterious impact on the development of a stable and healthy sense of self. The developmental theory proposed for the DID/taxon model is predicated on the belief that pathological levels of dissociation beginning early in life and operating across sensitive developmental periods produce a distinctly different type of psychological organization of self compared to low dissociative individuals. This theoretical model remains to be proven, but it is sufficiently well supported to provide a solid basis for the formulation of testable hypotheses.

Pathological dissociation has been included in the enigmatic category of an “experiment of nature,” in which scientific knowledge is gained through the suffering of individuals with a unique injury or illness that offers insight into the underlying workings of mind or body. Perhaps dissociation is more properly analogized to the Rosetta stone, which enabled the translation of silent hieroglyphics into a living language, thereby unlocking the latent information within the symbols. Dissociation is robustly connected to fundamental developmental antecedents and long-term psychopathological outcomes. Its developmental impact can be detected in cognition, memory, psychophysiology, neurobiology, and behavior. The relatively doable process of tracing these pathways in longitudinal studies offers enormous opportunities to understand fundamental mind-body-behavior questions across multiple levels of scientific inquiry. Few other psychological processes have been shown to exhibit such a profound range of correlations and effects on body and behavior. Our ability to identify markers of increased dissociation across methodological levels ranging from fMRI scans to cognition performance to psychophysiological reactivity to specific psychopathology offers an extraordinary opportunity to translate bodies of knowledge at one level of scientific inquiry to other levels. In doing so, much latent information should be revealed. It is this sense of possibility that is stimulating a growing interest in dissociation as a unique example of developmental psychopathology that offers to help reveal the causal linkages between early caretaking and environmental aversive experiences with adult psychopathology.

CHAPTER 19

Competence and Psychopathology in Development

ANN S. MASTEN, KEITH B. BURT, and J. DOUGLAS COATSWORTH

HISTORICAL ROOTS OF TWO TRADITIONS	697
Origins of Psychopathology Concepts	697
Influences of Darwin and Freud	698
Origins of Competence Concepts	698
Intelligence Theory and Assessment in the History of Competence	699
Ego and Self Psychology in the History of Competence	699
Self-Efficacy and Mastery Motivation in the History of Competence	700
Developmental Issues and Tasks in the History of Competence	701
Key Intersections in the History of Competence and Psychopathology	701
DEFINING COMPETENCE IN DEVELOPMENTAL PSYCHOPATHOLOGY	702
Key Themes among Competence Constructs	703
Key Issues in Conceptualizing Competence	703
A Working Definition of Competence	704
Developmental Tasks in the Definition of Competence	704
DEFINING PSYCHOPATHOLOGY IN RELATION TO COMPETENCE: IMPAIRMENT AND DISABILITY	706
Impairment and Adaptive Functioning	707
Controversies in the Role of Competence in the Classification of Psychopathology	709
MODELS AND PERTINENT EVIDENCE LINKING COMPETENCE AND PSYCHOPATHOLOGY	710
Confounded Meanings and Measures	711
Causal Models	712

The concept of adaptation is fundamental to developmental psychopathology as a comprehensive and integrative approach to understanding behavior in the context and course of development. Moreover, it is a fundamental premise of developmental psychopathology that understanding paths toward and away from positive development as well as psychopathology is crucial to the twin goals of promoting children's mental health and reducing or averting the damage and burden of suffering attributable to psychopathology in individuals, families, and society. The focus on adaptation and its vicissitudes in development has characterized developmental psychopathology from its inception, as this integrative perspective emerged in the second half of the twentieth century (Cicchetti, 1984, 1990a; Cum-

mings, Davies, & Campbell, 2000; Masten, 1989; Sroufe & Rutter, 1984). It follows from the history and tenets of this integrative and comprehensive perspective on psychosocial problems that developmental psychopathology would encompass the study of competence and resilience, positive adjustment, protective processes, and prevention along with investigation of problems, mental illness, treatment, and vulnerability (Cicchetti, 1984, 1989; Cicchetti & Cohen, 1995; Masten, 1989, 2001; Masten & Braswell, 1991; Masten & Coatsworth, 1995; Luthar, Chapter 20, this *Handbook*, this volume; Sroufe & Rutter, 1984).

The focus of this chapter is *competence* as it relates to psychopathology in development. In the first edition of this volume, our chapter also included *resilience* (Masten &

Coatsworth, 1995), but the burgeoning attention to competence *and* resilience over the past decades dictated devoting two chapters to these interrelated topics in this edition, one focused on competence and the other on resilience in developmental psychopathology.

Resilience refers to processes and patterns of positive adaptation in development during or following severe threats to adaptation. In many cases, the quality of adaptation as studied by resilience investigators is judged on the basis of competence criteria (Garmezy, 1974, 1987; Luthar, Chapter 20, this *Handbook*, this volume; Masten, 1989, 2001). Thus, the study of competence and the study of resilience are inextricably linked, with resilience focused more sharply on adaptation under extenuating circumstances of deprivation, trauma, disaster, or other acute and chronic adversities. This chapter emphasizes the meaning and history of competence and its historical, theoretical, and empirical links with psychopathology. The chapter by Luthar is focused on resilience and adaptation in relation to adversity and the vulnerability and protective processes that explain individual differences and development in the context of adversity.

The first section of this chapter describes the historical roots of the two traditions of competence and psychopathology. Given that so many other chapters of these volumes are focused on psychopathology, this section emphasizes the history of concepts most pertinent to competence. Similarly, the section on the history of competence emphasizes constructs that are most important for developmental psychopathology, particularly in relation to the history and definitions of psychopathology, its diagnosis, and interventions to prevent or treat mental health problems. Early roots of prevention science are also briefly examined in relation to the conceptual history of adaptation in development in this first section.

The second section of the chapter is focused on defining competence. Key themes and issues from the literature on competence constructs are summarized. A working definition of competence is presented, and the contemporary work on developmental task theory is examined.

In the third section, psychopathology is defined in relation to competence, with a particular focus on the concepts of impairment, harmful dysfunction, and disability in the definition and classification of mental illness. Selected measures of impairment are reviewed and controversies pertinent to competence are considered.

The fourth section delineates several models depicting how competence and psychopathology might come to be related. Confounded concepts and measures are addressed first, to consider how spurious connections might arise in

the literature. Then a sequence of causal models is presented and described, with examples. Common causal models include shared risk factors, common mediators, and a common underlying disorder influencing both competence and symptoms of psychopathology. Psychopathology and competence can also influence each other. The symptoms of psychopathology may cause competence problems, competence failures may contribute to psychopathology, and both of these can occur simultaneously or in sequence. Complex dynamic models are considered, with transactional, progressive, and cascade effects.

The fifth section of the chapter examines intervention efforts pertinent to competence, with an emphasis on prevention science, which is historically and conceptually related to both competence and psychopathology science. Examples of prevention research in which competence plays a major role are presented. The role of intervention designs is discussed as a strategy for experimentally testing models linking competence and psychopathology.

In the conclusion, we evaluate the progress made in developmental psychopathology toward integrating the study of positive and maladaptive development and discuss the implications for improving developmental science and its applications. We discuss the possibility of strategic developmental policy and prevention, built on a foundation of knowledge about competence and psychopathology in development. Finally, we describe exciting future directions and the potential benefit for stakeholders in the development of competence.

HISTORICAL ROOTS OF TWO TRADITIONS

The ideas and concepts encompassed by *competence* and *psychopathology* have old and somewhat overlapping origins. Ancient concepts pertinent to modern versions date back at least to classical Greek traditions in philosophy, government, and medicine (Masten & Curtis, 2000).

Origins of Psychopathology Concepts

Concepts of psychopathology have ancient roots in the history of medicine (Alexander & Selesnick, 1966; Menninger, 1963). In the school of thought associated with Hippocrates (460–377 B.C.), dysfunctions of body and behavior were attributed to imbalances in the four humors of the body (blood, phlegm, yellow bile, black bile), and one of the earliest known classification systems for mental illnesses was described. This system included categories for

epilepsy, mania, melancholia, and “paranoia” or mental deterioration (Alexander & Selesnick, 1966). Already present in this school of thought was the idea that brain dysfunction was involved in mental and behavioral problems. Yet, it would be 2,000 years before the science of mental disease began to flourish.

Modern concepts of psychopathology took hold in the late eighteenth and nineteenth centuries, as modern science and medicine emerged from the Renaissance and the Enlightenment. Behavior that had been observed centuries earlier began to be systematically studied and organized into classification systems by pioneers like Pinel and Kraepelin (Alexander & Selesnick, 1966; Menninger, 1963). At this time, more attention was given to the notion that diseases of the mind and behavior could be differentiated by their *course*, and, implicitly, the *quality* of functioning and the *development* of symptoms over time was given more importance in classification. Age of onset and course were recognized as significant by several nineteenth-century psychiatrists, including Kahlbaum and Savage (Menninger, 1963).

Also during this period, childhood disorders were described systematically by clinicians, who noted major distinctions in types of cognitive, behavioral, and emotional problems observed in children (Alexander & Selesnick, 1966). Esquirol observed differences between children with primarily mental functioning disabilities and those with psychotic symptoms (though not in these terms). Emminghaus observed that some childhood diseases appeared to result from physical causes, whereas others resulted from poor rearing conditions or excessive fear. Emminghaus also viewed childhood disorders as distinctly different from adult disorders, but the prevailing view of his time in the nineteenth century—an idea enduring well into the next century—was that many conditions of adults could be found in basically the same form in children.

The perspective that came to be called the *medical model*, based on the premise that psychopathology is caused by brain disease, dominated psychiatry in the nineteenth and early twentieth centuries, though there were occasional dissenters. Griesinger (1817–1868) is quoted by Menninger (1963, pp. 26, 454) in his history of psychiatry as stating that “mental diseases are brain diseases.” In contrast, Pierre Janet (1859–1947) would later take issue with the idea of organic dysfunction as the root of *all* mental health problems, noting that, whereas sometimes an automobile stops because it is broken, sometimes it stops because it is out of fuel (Menninger, 1963, p. 445).

Influences of Darwin and Freud

Two towering figures of the nineteenth century, Darwin and Freud, had profound influences on the concepts of psychopathology and competence; both of them, in different ways, spurred the study of behavior from the perspectives of adaptation and development (Alexander & Selesnick, 1966; Cairns, 1998; Masten & Coatsworth, 1995). Their influence is evident in the classification system of Adolf Meyer, who departed dramatically from the nineteenth-century disease model to promote a biosocial theory of psychopathology, conceptualizing psychopathology in terms of reactions of the whole organism to life experiences and stress (Kendell, 1975; Menninger, 1963). It is also evident in the classification system of Jelliffe and White, which included such disorders as shellshock as well as dementia praecox and manic-depressive disorder, which were described so vividly by pioneering psychiatrists (Menninger, 1963). By 1945, when Menninger (1963) synthesized the ideas of the time into a classification system for mental disorders, the system included neurotic and other reactive disorders that were not conceptualized strictly as brain diseases but also incorporated ideas about adaptation and trauma that stemmed from the theory of evolution and also psychoanalytic theory. This system, which was adopted with adaptations by the Veterans Administration in the United States, strongly influenced the first version of the *Diagnostic and Statistical Manual of Mental Disorders (DSM)*, published by the American Psychiatric Association in 1952. Subsequently, in revisions and critiques of the *DSM* system, many controversies have arisen about the definition of psychopathology in relation to impairment, organic dysfunction, and competence, as examined in following sections.

Origins of Competence Concepts

Concepts of competence also have roots in classical Greek thought and share some of the same origins as ideas about psychopathology (Masten & Coatsworth, 1995; Masten & Curtis, 2000). Plato, for example, in *The Republic*, made recommendations about the individual characteristics that would make a good ruler many centuries before such qualities would be assessed and studied systematically in the behavioral and social sciences.

Competence in developmental psychopathology generally refers to a broad family of constructs related to the effectiveness of individual adaptation in developmental context (Masten & Coatsworth, 1995). The systematic study of variations in the quality of adaptation in children

and adults dates to the nineteenth century and was heavily influenced by both Darwinian and Freudian theory (Borstelmann, 1983; Cairns, 1983; Masten & Coatsworth, 1995; Mayr, 1982). As Mayr noted, the idea of adaptation was transformed in the nineteenth century from a static concept (reflecting a perfect harmony in nature) to a dynamic concept. Natural selection of individuals who varied in heritable ways provided the mechanism for evolution. The ego in Freudian theory was assigned the task of coordinating internal and external adaptation, balancing the personal (and often unconscious) needs of the individual with the requirements for getting along in society. Anna Freud, Heinz Hartmann, Erik Erikson, John Bowlby, and others extended and elaborated classical psychoanalytic theory to describe the processes and developmental course of adaptive functioning in children and adolescents (and adults; see Masten & Coatsworth, 1995). These ideas had a profound influence on subsequent theories about adaptation and competence, particularly on the concepts of *ego resiliency*, *intelligent behavior*, *mastery motivation*, *self-efficacy*, and *developmental tasks*.

Intelligence Theory and Assessment in the History of Competence

In the study of individual differences and personality in psychology, two prominent conceptual clusters have focused on individual differences in the quality of psychological functioning pursuant to successful adaptation: concepts about *intelligence* and concepts about *ego*. Over the years, theories about intelligence explicitly or implicitly encompassed the capacity for adaptation to the environment and adaptive behavior (see Masten & Coatsworth, 1995). Alfred Binet (Binet & Simon, 1905/1916; Sattler, 1988) believed that intelligence was a collection of abilities that included judgment, common sense, initiative, and the ability to adapt to circumstances. Jean Piaget viewed intelligence in cognitive development variously as “a particular instance of biological adaptation” and as “the form of equilibrium toward which successive adaptations and exchanges between the organization and the environment are directed” (quoted in Ginsburg & Oppen, 1988, p. 13). Piaget’s concepts of assimilation and accommodation in cognitive development were fundamentally processes of adaptation (Flavell, 1963). David Wechsler (1958, p. 7) defined intelligence broadly as “the aggregate or global capacity of the individual to act purposefully, to think rationally and to deal effectively with his environment.” Developmental ethologist William Charlesworth (1978,

1979) argued that we could infer intelligence (the internal disposition) from intelligent behavior, which referred to behaviors under cognitive control that were utilized to solve problems pertinent to an individual’s survival. Robert Sternberg (1985, p. 45) described intelligence as “mental activity directed toward purposive adaptation to, and selection and shaping of, real-world environments relevant to one’s life.”

The importance of adaptive success for defining intelligence has been recognized most influentially through the diagnostic criteria and related assessment tools for identifying mental retardation. A diagnosis of mental retardation requires evidence not only that cognitive functioning is well below average but also that there is adaptive impairment (American Psychiatric Association, 2000). Edgar Doll (1935, 1953), creator of the Vineland Social Maturity Scale (an instrument still widely used to determine level of adaptive functioning), believed that the essential requirement for defining mental deficiency was not performance on a standardized test of intellectual functioning, but whether the individual could function independently in the world. Doll argued that adaptive behavior, what he termed “social competence,” was evident only in manifest, typical performance in the environment. The view that mental retardation must include some degree of observable failure to adapt to specific environments gained wide acceptance, though debate continued about how to measure adaptive behavior (McGrew & Bruininks, 1989). At present, the influential American Association of Mental Retardation (see www.aamr.org) defines mental retardation as a disability originating by age 18, “characterized by significant limitations both in intellectual functioning and in adaptive behavior as expressed in conceptual, social, and practical adaptive skills” (http://www.aamr.org/Policies/faq_mental_retardation.shtml).

Ego and Self Psychology in the History of Competence

The concept of the *ego*, so prominent in psychoanalytic theory, has many permutations, but all concern adaptation. In Freudian theory, the concept of ego evolved and changed over time, although the function of the ego in psychoanalytic theory is always centered on adaptation. In *The Ego and the Id*, S. Freud (1923/1960) described his later conceptualization of the ego as a mental structure that served the purpose of both self-preservation and adaptation to the world. The ego functioned to resolve conflicts among needs or instincts, one’s conscience, and the environment; if the ego did not

succeed in this balancing act, unconscious conflict would produce the symptom of anxiety. A major goal of therapy in this regard was to strengthen the functioning of the ego. Freud's daughter, Anna Freud (1936/1966), elaborated the adaptive functions of the ego in terms of defense mechanisms, which were viewed as psychologically healthy. Heinz Hartmann's (1939/1958) landmark volume, *Ego Psychology and the Problem of Adaptation*, also elaborated the development and functions of the ego; he viewed adaptation and achievement in the external world as hallmarks of mental health. His contemporary, Ives Hendrick (1942), proposed that there must be an "instinct to master" the environment in addition to the pleasure-seeking instincts that psychoanalytic theory up to that time had emphasized.

These early psychoanalytic theorists set the stage for further advances in ego theory by Erik Erikson, Jane Loevinger, and Jeanne and Jack Block. Erikson (1963, 1968) focused on the adaptive nature of the ego and the processes of adaptation over the life span, describing sequential stages of psychosocial ego development that became the bedrock for developmental task theory (discussed later in the chapter). Erikson's well-known epigenetic theory outlined eight stages of development over the life course, each with a focal crisis or issue to address and resolve, such as trust in infancy and identity in adolescence. Each issue remained a task throughout life but rose to ascendancy during a particular epoch of development. Fundamental to his theory was the idea that adaptive responses to the issue of a developmental period would equip the individual well for the future. Like Erikson, Loevinger (1976) proposed sequential stages of ego development. In her theory, ego development encompassed the processes by which individuals organize and find coherence in their cognitions, affects, and behaviors, and she proposed a typology of personality based on individual differences in levels of ego development within an age cohort. Jack Block and Jeanne Block (1980) also proposed a personality theory based on ego functioning. The adaptive functions of the ego were differentiated in their theory in the concepts of *ego control* (referring to the modulation of impulses) and *ego resiliency* (referring to the modulation of one's behavior to meet contextual circumstances). Individuals could be maladaptive in terms of undercontrolling or overcontrolling impulses as well as due to low ego resiliency.

Self-Efficacy and Mastery Motivation in the History of Competence

The work of Hartmann and the other early psychoanalytic theorists also set the stage for the theories of Robert White, Susan Harter, and Albert Bandura, among others, on com-

petence, mastery motivation, and self-efficacy (Masten & Coatsworth, 1995). In a seminal essay, "Motivation Reconsidered: The Concept of Competence," White (1959) argued that humans and animals were motivated to master the environment as part of their evolutionary heritage. In a brilliant integration of developmental and evolutionary theory and observations of animal and child behavior, White suggested that humans and animals are biologically predisposed to interact with the environment in ways that promote effective adaptation, exploring and learning even when they are not motivated by hunger, thirst, pain, anxiety, or sexual desires. White termed this motivation *effectance* and the feelings of satisfaction associated with this motivation *efficacy*. In other words, people are motivated to be effective in their interactions with the environment, and they are motivated by the feelings of pleasure that follow successful interactions (or their perception). Harter (1978) later elaborated on the role of self-perception, the types of competence, and the role of failure in her extensions of mastery motivation theory. Harter proposed a model for effectance motivation that differentiated three domains of competence (cognitive, social, physical) and that included processes by which success or failure influenced motivation. Harter attempted to fill in the broad strokes of White's theory, linking his ideas to psychological concepts of the self, self-perception, intrinsic and extrinsic motivation, locus of control, and perceived competence. Connell and Wellborn (Connell, 1990; Connell & Wellborn, 1991) extended these ideas further to argue that people have psychological needs for competence, autonomy, and relatedness, which motivate many interactions with the environment.

The self-efficacy theory of Albert Bandura (1977, 1982, 1989, 1997) has focused on the role of perceived effectiveness in adaptation and related processes in human development, describing how beliefs about such effectiveness, what he termed *self-efficacy*, arise from interactions with the environment and influence subsequent adaptive behavior. This is a theory about human agency and the role of the beliefs people hold about "their capabilities to produce desired effects by their actions" (Bandura, 1997, p. vii). Successful adaptation engenders confidence, and confidence engenders subsequent adaptive efforts, though beliefs can be influenced or altered in many ways. Cognitive, affective, and motivational processes are linked in this model, which has been supported by elegant experiments (Bandura, 1997). Robust self-efficacy arises from experiences of overcoming manageable setbacks and challenges in life, and people with a positive and sturdy sense of their own efficacy are more likely to persevere in the face of failure.

Beliefs about one's efficacy include beliefs about one's control over experience. In Bandura's theory, if people do not believe they have any influence on what happens, they will lose the motivation to try to make things happen. Attributions about the self and control and their influence have been central to several lines of work related to self-efficacy. A maladaptive cousin to self-efficacy in the history of competence-related concepts is the notion of "learned helplessness" (Abramson, Seligman, & Teasdale, 1978; Garber & Seligman, 1980; Seligman, 1975). In the later versions of the learned helplessness theory, attributing one's failure to stable, global, and internal causes is expected to produce depressive affect (Abramson et al., 1978). Other scholars have argued that perceived control of successes and failures in adaptation has important influences on the self, mood, and subsequent motivation (Connell & Wellborn, 1991; Harter, 1985; Skinner, 1991; Skinner, Chapman, & Baltes, 1988). Generally, in this cluster of theories about self and self-efficacy, attributions about one's failure can lead to negative moods and self-concepts as well as diminished motivation to adapt, and more favorable attributions can contribute to positive moods and self-concepts and increased motivation.

Developmental Issues and Tasks in the History of Competence

The evaluation of effective adaptation, whether by self or others, requires criteria. The concept of *developmental tasks* focused attention on the developmental nature of the standards by which success in adaptation is judged. The idea of developmental tasks was anticipated in Sigmund Freud's psychosexual theory and subsequently in Erikson's theory of psychosocial development and in various elaborations of ego development (see Masten & Coatsworth, 1995). However, it was Robert Havighurst who articulated the role of developmental tasks in expectations, education, and society in an influential series of lectures and publications. Havighurst (1972) introduced his ideas about developmental tasks in a 1948 pamphlet designed for a course he was teaching at the University of Chicago. He proposed that living in society imposed on individual members a series of tasks to learn and accomplish in order to gain approval and rewards. These expectations become the basis for both self and society to judge whether a person is reasonably successful. Havighurst was primarily interested in the educational implications of developmental tasks and the role of the educational system in helping children accomplish the tasks. Nonetheless, like Erikson, Havighurst outlined a series of tasks over the life course. In earlier pe-

riods of development, tasks included learning to walk, talk, read, and distinguish right from wrong. In later periods of development, tasks included starting a family, civic responsibility, and adjusting to retirement. His age-graded developmental tasks were grounded in middle-class, American values of his time (Oerter, 1986).

Following Havighurst and Erikson, a series of developmental theorists built on their ideas and generated developmentally sequential lists of tasks and issues over the life course. The salient developmental issues of infancy and early childhood, for example, were delineated by Greenspan (1981), Sander (1975), Sroufe (1979), and Hill (1980, 1983) described the developmental challenges and tasks of adolescence.

Around this time, Waters and Sroufe (1983), in a seminal paper, integrated the construct of competence into an organizational theory of development, conceptualizing competence as a broad developmental construct. In their view, competence referred to an individual's ability to coordinate psychological functioning (behavioral, affective, cognitive) and environmental resources to achieve developmental goals. Developmental tasks played a central organizational role in their thinking, in that mastering the challenges posed by these issues reflected the capacity to coordinate behavior in adaptive ways and also set the stage for future competence. They predicted that competence in developmental tasks would show coherence through time, even as the nature of developmental issues and challenges changed. They also argued that the best measures of competence, and those with the best predictive validity, would be broad in scope, tap success in regard to age-salient developmental issues, hence requiring coordinated behavior, and also reflect naturally occurring challenges. Subsequently, developmental task theory (discussed later in the chapter) would be expanded to encompass the contextual features of such tasks and to address the importance of task success for defining successful and unsuccessful adaptation, both for competence and psychopathology.

Key Intersections in the History of Competence and Psychopathology

The histories of competence and psychopathology did not unfold independently. There were important points of intersection early in their respective histories, both in relation to science and practice. Scientists and clinicians attending to the course of psychopathology noticed the significance of premorbid competence for the outcomes of their patients, whereas others concerned with preventing mental health problems in youth began to notice the effectiveness

of early interventions to promote competence as a strategy for preventing mental illness.

Premorbid Competence in the History of Psychopathology

A key intersection in the history of ideas pertaining to competence and psychopathology was the notion of *pre-morbid competence* in studies of risk and psychopathology (Feffer & Phillips, 1953; Garmezy, 1970; Phillips, 1953, 1968; Phillips & Cowitz, 1953; Zigler & Glick, 1986). Clinicians had long noted that patients who had a better track record of success in expected adaptive functioning for people of their age and situation prior to the onset of mental illness had better prognosis. Experimental psychopathologists, conducting studies to document the role of what they termed premorbid competence, developed measures of individual success in age-appropriate adaptive tasks, such as the Phillips Premorbid Scale of Adjustment (Phillips, 1953) and its successor, the Zigler-Phillips Social Competence Scale, that demonstrated predictive validity (Zigler & Glick, 1986; Zigler & Phillips, 1961). These tools focused on adult tasks, such as success in marriage and work, long recognized as hallmarks of good adult adjustment, as evident in the famous answer by Sigmund Freud to a question about what a normal adult should be able to do well: “Lieben und arbeiten” (to love and to work; as recounted by Erik Erikson, 1968, p. 136).

Child Welfare, Mental Hygiene, and the Early History of Prevention

Another important intersection in the history of competence and psychopathology can be traced to late nineteenth- and early twentieth-century child guidance and mental hygiene movements, which gave rise to the first mental health prevention efforts and community psychology (Coie, Miller-Johnson, & Bagwell, 2000). Founded in part through the efforts of seminal figures Clifford Beers and Adolf Meyer, these dual movements were committed to promoting mental health and to the humane treatment of individuals with mental illness. Their efforts focused on changing the system, delivery, and practices in mental health services within the framework of a broad public health perspective. The methods behind these movements were founded mainly in public health and focused primarily on changing the broad environmental factors purportedly associated with problem behavior and on altering the systems of care for individuals with mental illness and early behavior problems. The child guidance movement extended such efforts to work with families to enhance child mental health and development, and research institutes

were founded to study child development and to educate parents, often with the explicit goal of improving children and preventing future problems:

There began a great interest in children and a belief that by starting early we could improve people greatly, and perhaps avoid some of the personality difficulties of adults. It seemed highly desirable to study children and to develop new patterns of child care and rearing, and preschool education. (L. K. Frank, 1962, p. 207)

The child guidance movement had as one of its stated goals the prevention of juvenile delinquency (Horn, 1989). Primary prevention became a focus of psychiatry and psychology significantly later than it did for public health (Caplan, 1964). During the emergence of community psychology directed at mental health during the 1950s and 1960s, aspects of a public health perspective were adopted, including the term *prevention* itself, along with concepts of primary, secondary, and tertiary prevention, which differentiated intervention efforts aimed before, during, or after the emergence of significant psychopathology (Coie et al., 2000). Subsequently, prevention efforts would be differentiated more often on the basis of target population, as suggested by Gordon (1983): *universal* (targeting general public), *selective* (targeting those at presumed risk for the problem of interest), and *indicated* (targeting those at high risk but not yet clinically disordered). The influential Institute of Medicine Report of 1994 recommended Gordon’s approach to classifying preventive interventions, with some modifications (Mrazek & Haggerty, 1994).

Central to the early prevention models was the idea of facilitating capacity for social and interpersonal behavior that would help individuals maintain functioning despite life crises. Strategies included both *social engineering* and *competence enhancement* programs. Among the earliest social competence-promotion efforts on record (beyond public education itself) was a program developed by Ojemann and colleagues (Ojemann, Levitt, Lyne, & Whitesie, 1955) to help children develop causal thinking, a precursor to many of the social problem-solving approaches commonly used in today’s prevention programs.

DEFINING COMPETENCE IN DEVELOPMENTAL PSYCHOPATHOLOGY

During the last two decades of the twentieth century, the concept of competence underwent a renaissance as developmental psychopathology emerged (Cicchetti, 1987; Cicchetti & Cohen, 1995; Cicchetti & Toth, 1995; D. H. Ford, 1987;

Garmezy, 1987; Garmezy & Masten, 1986; Garmezy, Masten, & Tellegen, 1984; Masten & Coatsworth, 1995; Masten & Curtis, 2000; Sroufe, 1979, 1997; Waters & Sroufe, 1983). As attention focused on theories of competence and how to judge success or failure in behavioral development, key themes and issues emerged (D. H. Ford, 1987; Masten & Coatsworth, 1995).

Key Themes among Competence Constructs

As noted in our chapter in the first edition of this handbook (Masten & Coatsworth, 1995), competence-related concepts encompass a diverse array of ideas and phenomena. Yet, there are common themes across these constructs, consistent with a meaningful family of ideas. Competence concepts share the following assumptions: (1) There are behaviors and related processes consistently related to the effectiveness of adaptation in the environment; (2) there are individual differences in effective behavior that can be evaluated; (3) there are developmental changes in the behaviors associated with effective adaptation; (4) adaptation requires coordination and integration of multiple functions in the organism to achieve purposive goals; (5) many processes are involved in facilitating effective functioning in the environment; and (6) some of these processes reflect intraindividual processes, whereas others reflect interactions of an individual with the many systems in which the individual organism develops, including relationships with other people.

We also noted differences among members of the broad family of competence constructs (see Masten & Coatsworth, 1995, p. 723). Concepts and theories about competence differ in several major ways. Though all competence family constructs focus on effective adaptation in the environment, some focus on internal adaptation or behavior, others focus on external behavior, and still others focus primarily on interactions or relationships. Considered from a systems perspective, such differences could be viewed as focusing attention on different aspects of system dynamics: Some focus on how a living system maintains its own equilibrium across development, some focus on the transactions of the individual organism with the other living systems in its milieu, and some focus on whether the system is adapting to its environment. Accordingly, ideas vary in terms of their focus on levels of analysis, with some competence concepts focused on individual functioning and others focused on competence in social interactions, family process, or the context of larger ecological systems. Competence constructs also vary in focus on processes versus attributes or outcomes. As a final

example, competence constructs also vary in scope from very broad to narrow domains of functioning.

Key Issues in Conceptualizing Competence

Key issues also emerged as scholars revisited competence concepts in developmental psychopathology (M. E. Ford, 1985; Masten & Coatsworth, 1995; Waters & Sroufe, 1983). One major set of issues concerns *who decides the criteria*. Evaluating the effectiveness of adaptation requires criteria that can be expected to vary by perspectives and context, including culture and period of history and who is doing the judging and for what purposes.

A second set of issues concerns *when to judge success*. Success can be judged by short-term criteria or by long-term adaptive success. It is conceivable that behavior appearing to be successful over the short term has negative long-term consequences. It is also conceivable that a person who fails now can turn around and succeed later. Waters and Sroufe (1983) argued that the criteria for evaluating competence from a developmental perspective must include both proximate and ultimate criteria of adaptation. If adaptations worked in the short term but compromised future development, a child would not be viewed as competent by their standards. Presumably, widely held developmental task expectations, particularly those held across cultures, have been recognized over time not only as markers of current effectiveness but also as important harbingers of future adaptation in society.

Another set of issues concerns *broad versus narrow criteria*, or *multidimensional versus one-dimensional success criteria*. Clearly, competence can be defined in broader and narrower ways (a competent child versus a child who is a competent mathematician). Broad definitions of competence typically require either integrated functioning or success in multiple domains. Even narrow-focused judgments about competence typically presume the coordinated functioning of many processes to achieve and execute the competent behavior, such as the processes involved in reading, spelling, and solving mathematical problems.

Level and consistency of achievement is another cluster of issues found in competence constructs and assessment. Does competence refer to high levels of effectiveness, or adequate levels? Does competence refer to relative achievement (better than others or better than average), or absolute standards? Does one need to be doing well in multiple domains all the time, or in only some domains most of the time? Investigators have taken different positions on these questions in their theoretical and operational definitions of competence.

Capacity versus performance issues are related to consistency and also to internal versus external criteria. The capacity for effective adaptation can be inferred from indicators such as intelligence and personality tests or from a track record of past effectiveness as observed or reported. There have been debates about whether competence refers to a personal aptitude (or trait), something a person *has*, or to a pattern of observably effective behavior, something a person *does*, over time in relation to (and often supported by) the context. In either case, however, competence always involves an inference about effectiveness, past or expected.

A Working Definition of Competence

With these themes and issues in mind, we define competence in developmental psychopathology broadly as follows:

Competence refers to a family of constructs related to the capacity or motivation for, process of, or outcomes of effective adaptation in the environment, often inferred from a track record of effectiveness in age-salient developmental tasks and always embedded in developmental, cultural, and historical context.

This definition is closely related to definitions of competence articulated by us with other members of the Project Competence research team over the years (Masten & Coatsworth, 1995; Masten & Curtis, 2000; Masten et al., 1995, 1999) and it has been influenced by numerous mentors and colleagues (M. E. Ford, 1985; Garmezy, 1971, 1974; Garmezy & Nuechterlein, 1972; Hartmann, 1939/1958; Phillips, 1968; Sroufe, 1979; Waters & Sroufe, 1983; White, 1959; Zigler & Glick, 1986). By this definition, competence is inherently multidimensional, contextual, and developmentally dynamic. This definition requires criteria by which to judge the success of meeting standards for behavior related to adaptive functioning in society and also suggests that the appropriate criteria for general competence are “doing adequately well” in age-salient developmental tasks (described further, later in the chapter). It assumes that competence is a judgment about a behavioral pattern over time, based on generalizations about a track record, and allowing for instances of poor performance. It assumes that the expectations for individual behavior change with development and over historical time and may vary across cultures. An individual who shows such a pattern is presumed to have the capacity for future competence, though this capacity may reflect relationships and resources as well as individual aptitudes or

skills; hence, to call an individual “competent” means that he or she has manifested behavior that leads one to expect future competence.

This definition is broad, reflecting a global judgment that life for this individual is going okay in the expected ways necessary for positive adaptation in the individual’s ecological and historical situation. Competence can also be used more narrowly to refer to more specific domains, as in academic competence, or even more narrow subdomains, such as reading competence. In addition, competence by this definition may be influenced by many ongoing processes within the organism, or between the organism and the environment, in relationships with other people or other kinds of transactional interactions with the environment. Therefore, general or specific competence could be undermined or destroyed by damage to the organism, problematic relationships or transactions with the environment, traumatic life experiences, and many other processes that affect the capacity for adaptation and achievement in relevant domains.

Developmental Tasks in the Definition of Competence

As noted, scholars of diverse persuasions have recognized the importance of broad, developmentally based standards for behavior and achievement in the concepts of developmental tasks or issues, following the lead of Havighurst (1972) and the organizational-developmental theorists (e.g., Sroufe, 1979). These tasks are akin to psychosocial milestones of development, broad indicators of how well adaptation and adjustment in development are proceeding from a societal point of view. Clearly, such standards would be expected to change as a function of major changes in culture and to vary across cultures and dramatically diverse contexts. Thus, the expectation that a child will learn to hunt for meat effectively might be a key task for a male youth in a hunter society and completely unimportant for a girl in the same society or any youth in an urban, technological society. At the same time, one would expect some developmental tasks to occur across cultures and time because they reflect the characteristic developmental course and adaptive attributes of the species. Examples include learning to talk, to control anger, and to attach to other people.

Various lists of developmental tasks have appeared over the years (see Erikson, 1963, 1968; Havighurst, 1972; Hill, 1980; Klaczynski, 1990; Masten & Braswell, 1991; Masten & Coatsworth, 1998; Sroufe, 1979; Waters & Sroufe, 1983). These lists show striking similarities, reflecting a

general consensus on age-salient developmental tasks, at least in the developmental literature of contemporary industrial/technological societies. A list of broad developmental tasks is shown in Table 19.1.

In the Project Competence research program, we have argued that there are a small number of readily identifiable task domains of expected engagement and achievement for a given age cohort, time, and culture, and these wax and wane in salience across developmental periods and contexts (Masten & Coatsworth, 1995, 1998; Masten et al., 1999; Roisman, Masten, Coatsworth, & Tellegen, 2004). In line with the perspectives of the early developmental task theorists (Erikson, 1963, 1968; Sroufe, 1979; Waters & Sroufe, 1983), we believe that doing adequately well in core developmental domains of one developmental period is a harbinger

of future successful adaptation and development, even for domains that have not yet emerged as important (Roisman et al., 2004). This conclusion follows from observing that age-salient core expectations are being met, because this kind of success indicates that development is proceeding in the right direction with adequate adaptive capacity, resources, and support. In contrast, it is not as important how well one is doing in not yet salient, still-emerging domains. Thus, for example, in contemporary U.S. society, we would expect eventual success in work and romantic relationships (salient adult developmental tasks) to be forecast better by the quality of academic achievement and friendships in adolescence, which are core developmental task domains, than by the quality of work achievement and romantic relationships during adolescence, when these are emerging task domains (Roisman et al., 2004).

Many life experiences may influence the achievement of these tasks, ranging from dysfunctions of the organism to symptoms of disease or disorder, bad choices, and overwhelming negative life events. It is possible that many kinds of social interference by other people, ranging from discrimination to child abuse, could interfere with achieving these tasks. Anything that restricts the opportunities to engage these tasks or accomplish them can create difficulties, not only for present well-being but well into the future, if mastering these tasks reflects skills, knowledge, resources, or credentials that at some level are required for success in the future tasks.

Children who appear unable to accomplish or have great difficulty accomplishing age-salient developmental tasks or meeting associated expectations on time (normatively speaking) would be expected to generate concern in parents, teachers, and other people in the community; similarly, perceived failure in these tasks could be expected to generate distress or concern in the individual person as well. For example, an infant who does not show any signs of bonding with parents during the 1st year or a toddler who does not acquire any language would concern most parents everywhere. In many societies worldwide, there would also be concern about a school-age child who refused to go to school or is not able to read after years of instruction. Also in most societies, a young adult who does not do any kind of work, inside or outside the home (nor follow any alternative, approved life course), would also likely cause concern to parents and community members.

Not surprisingly, the quality of functioning in age-salient developmental tasks also constitutes the implicit or explicit criteria by which *impairment* is judged in the diagnosis of psychiatric disorders in major classification

TABLE 19.1 Developmental Tasks of Early Life in Contemporary Industrial Societies

Infants, Toddlers, Nursery School-Age Children

Attachment to one or more specific adults.
Learning to sit, stand, walk, run, and jump.
Acquiring functional language.
Obedience to simple commands and instructions of adults.
Toilet training.
Self-control of proscribed physical aggression (e.g., not biting people).
Appropriate play with toys and other people.

Young School-Age Children

Learning to read and write a language.
Learning basic mathematics.
Attending and behaving appropriately at school.
Following rules for behavior at home, at school, and in public places.
Getting along with peers in school.
Making friends with peers.

Adolescents

Attending and behaving appropriately at school.
Learning to solve problems with numbers, algebra.
Learning required language, history, and other subjects.
Completing a course of secondary schooling.
Getting along with peers in school.
Making and maintaining close friendships.
Obeying the laws of the society.

Young Adults

Working or preparing for future in higher education (or caring for a family).
If working: behaving appropriately in the workplace.
If in school: meeting academic standards for courses or degrees.
If a parent: taking care of child or children.
Forming and maintaining romantic relationships.
Obeying the laws of the society.
Learning to maintain a household.

systems. The quality of functioning in these tasks is embedded in these systems in other ways as well. The following section addresses the role of competence in the definition and diagnosis of psychopathology.

DEFINING PSYCHOPATHOLOGY IN RELATION TO COMPETENCE: IMPAIRMENT AND DISABILITY

The theme of competence is connected to the *DSM* of the American Psychiatric Association through the manual's definition of mental disorder as well as through criteria sets for particular disorders, associated impairments and nondiagnostic codes, and Axis V of the multi-axial classification system. The most recent revision of the manual retains the basic definition of mental disorder adopted in the third edition (*DSM-III* and *DSM-III-R*), as follows:

a clinically significant behavioral or psychological syndrome or pattern that occurs in an individual and that is associated with present distress (e.g., a painful symptom) or disability (i.e., impairment in one of more important areas of functioning) or with a significantly increased risk of suffering death, pain, disability, or an important loss of freedom. (American Psychiatric Association, 2000, p. xxxi)

The disorder must also not be an expectable or culturally sanctioned response to an event and must be considered as some sort of "behavioral, psychological, or biological dysfunction in the individual" (p. xxxi). However, the manual's introduction notes that there is no precise boundary to the construct of *mental disorder* and that disorders can be represented at various levels of analysis and abstraction.

Perhaps the most notable way competence concepts enter into the *DSM* classification system is in the requirement of significant distress or impairment and dysfunction in the individual (Masten & Curtis, 2000). During the *DSM-IV* revision process, variants of this so-called clinical significance criterion were added to criteria sets of approximately 70% of *DSM* disorders in an attempt to rectify what many felt was an abundance of false-positive cases (Wakefield & First, 2003). In addition, however, many disorder criteria require specific impairments that are connected to age-salient developmental tasks. For example, a diagnosis of a learning disorder requires significant interference with academic achievement; a diagnosis of Mental Retardation requires impairment in at least two of several competence-related areas, such as social skills, academic skills, and work; and diagnosis of Pervasive De-

velopmental Disorder often requires qualitative impairment in social interaction and/or language skills (Masten & Coatsworth, 1995; Masten & Curtis, 2000). Finally, as discussed in more detail later in the chapter, the use of a global assessment of functioning (GAF) scale (Axis V) represents an explicit acknowledgment of the interrelationship of competence and psychopathology by the authors of *DSM*.

There is widespread consensus that the construct of mental disorder has eluded precise delineation, at least to date, and debate over its definition and scope has continued over the recent past. Most discussions center on Wakefield's harmful dysfunction analysis (HDA; Wakefield, 1992a, 1992b, 1999, 2001, 2003), which proposes two necessary conditions for the presence of a mental disorder: (1) failure of a natural, evolutionarily selected function in the individual that (2) causes harm to the individual or to society. This analysis dovetails closely with the official definition included in the *DSM*, and calls have been made to incorporate the HDA explicitly into the definition of mental disorder in *DSM-V* (Spitzer, 1999; Wakefield & First, 2003). Critics of Wakefield's proposal have offered alternative conceptions of disorder as a fuzzy-bounded Roschian prototype (Lilienfeld & Marino, 1995, 1999) and as any condition that significantly interferes with an organism's deliberate action (Bergner, 1997). Others have focused on potential weaknesses in the HDA analysis or have argued against attempts to provide an absolute definition of mental disorder that consists of separate factual and evaluative components (Fulford, 1999; Kirmayer & Young, 1999).

However, most of the current debate around Wakefield's proposal and the definition of mental disorder has centered on the concept of *dysfunction* and the pitfalls inherent in basing it in evolutionary theory (e.g., Houts, 2001; Sadler, 1999). Indeed, the attempt to provide an operational definition of the term "dysfunction" is perhaps the most notable way in which the HDA extends the *DSM* definition. Less controversial in most debates is the idea that disorder requires some harm or distress for the individual, and that judgments of harm often require inclusion of value considerations. It is this conception of harm, and closely related ideas of impairment and disability, that seem closest to the definitions of competence outlined in the previous section.

The construct of *functional impairment* is central to the harm component of the *DSM* definition of mental disorder. In the psychiatric literature, symptoms and impairment have traditionally been seen as closely related but nonetheless independent constructs (Lehman, Alexopoulos, Goldman, Jeste, & Üstün, 2002). Lehman et al. note that in

DSM-III, raters of adaptive functioning were instructed to focus on three areas: social relations, occupational functioning, and use of leisure time. However, despite research emphasizing the measurement of functional impairment as a multidimensional construct, in *DSM-III-R* and more recent revisions adaptive functioning has been changed to the single GAF scale. In addition, users of the GAF are instructed to consider both symptom severity (i.e., psychological functioning) and level of social and occupational functioning and to assign the lower score if the two judgments are discrepant. Although such aggregation may improve prediction of service utilization, it does not provide conceptual clarity to relations between symptoms and competence. Historically, as noted earlier, part of the motivation for inclusion of impairment ratings in the diagnostic system was the belief that individuals tended to return to premorbid levels of functioning following a circumscribed disorder episode (Masten & Coatsworth, 1995).

Within the *DSM* framework, a common assumption is that psychiatric symptoms are the cause of functional impairment. For example, Lehman et al. (2002) take the example of an individual diagnosed with Schizophrenia to illustrate how basic dysfunctions (e.g., disorganized thought processes) can lead to functional impairment (e.g., impaired social relationships due to inability to speak in coherent sentences). Although this example captures one potential mechanism by which competence and symptoms might be connected, more ambiguous situations can easily be conceived, as demonstrated by Richters and Cicchetti (1993) in their discussion of the mental disorder status of Conduct Disorder. As they note in this penetrating and witty paper, it is not that easy to determine whether the misbehavior of the young Samuel Clemens (author Mark Twain) and friends, fictionalized in the adventures of Tom Sawyer and Huckleberry Finn, should be diagnosed as psychopathology.

In contrast to the American *DSM* system, the World Health Organization's (WHO; 1992) *International Classification of Diseases (ICD-10)* does not present a generic definition of mental disorder. In addition, the "clinical significance criterion" noted earlier is not included in *ICD-10* criteria sets. Instead, the WHO has commissioned work groups to create and research a separate system for the assessment of functional impairment and disability. This has resulted in the WHO's (2001) Disability Assessment Schedule, which attempts to classify the activities of a person across several categories: cognition, mobility, self-care, interpersonal interactions, leisure and work, and participation in community activities. Thus, the *ICD* sys-

tem explicitly and deliberately attempts to separate the question of impairment from disorder judgments.

Impairment and Adaptive Functioning

In providing a context for discussing relationships between competence and psychopathology, it is beneficial to examine more closely how functional impairment has been assessed and measured in psychological and psychiatric research. As Canino, Costello, and Angold (1999, p. 94) have pointed out in a review of impairment instruments, "The area under the label 'functional impairment' is wide and poorly bounded, shading off into areas that have their own armamentarium of measures." Canino et al. note the issue of impairment and competence potentially representing opposite ends of the same continuum in many areas and discuss the need for measures developed in particular contexts that capture cultural as well as developmental differences.

One closely related area of research not directly touched on by most reviews of functional impairment is quality of life (QL). In this area, researchers often distinguish between general QL and health-related QL (the latter exemplified by symptom- and disease-specific measures, such as those that have been developed for asthma, cancer, epilepsy, diabetes, and other physical conditions; Eiser & Morse, 2001). Although QL research has evolved largely independently of research on functional impairment, similarities exist between these systems of measurement that make cross-disciplinary links increasingly likely. Typically, however, general QL represents a broader conceptual space than either impairment or competence, incorporating those constructs but also including domains such as material well-being (e.g., physical safety, housing quality, availability of transportation) and emotional well-being (e.g., faith, fulfillment, self-esteem; Wallander, Schmitt, & Koot, 2001). Debates in the QL literature include whether QL can be represented as a holistic, universal concept versus one that is specific to particular groups of children (such as those with a particular health condition), which particular domains represent QL most definitively, and whether objective or subjective assessments (or both) should be given primacy (Wallander et al., 2001).

In the psychological research tradition on functional impairment, a useful way of grouping assessments is one-dimensional versus multidimensional scales. No doubt due in part to concerns over professional staff burden, the *DSM* system has employed one-dimensional scales under Axis V that are designed to be completed rapidly by a clinician fa-

miliar with the individual being rated. *DSM-IV* retains the GAF for Axis V but also includes two related one-dimensional scales under appendixes for further study: the Social and Occupational Functioning Scale (SOFAS) and the Global Assessment of Relational Functioning (GARF). The GARF assigns anchor points based on a continuum of functioning in a relational unit, instructing the clinician to consider domains of problem solving, organization, and emotional climate. The SOFAS is akin to the GAF with symptom content removed, and thus appears to be the closest approximation to a competence scale produced by the *DSM* system. It is of note that the original version of Axis V from *DSM-III* (American Psychiatric Association, 1980, pp. 28–30) required the clinician to rate the highest level of adaptive functioning in the past year (not symptoms), using a 7-point scale and taking into consideration social functioning, occupational functioning, and use of leisure time (listed in order of designated importance).

Despite its designation as worthy of further study, there is little recent research that specifically addresses the psychometric and predictive properties of the SOFAS. One recent study presents predictive validity information for the three unidimensional scales and supports the view that the SOFAS may have better predictive validity of future illness and impairment (correlations with future GAF and severity scales) than the GAF itself; the authors suggest that this is because the SOFAS measures a narrower construct (Hay, Katsikitis, Begg, Da Costa, & Blumenfeld, 2003). Hilsenroth et al. (2000) report that all three main Axis V scales show good interrater reliability and that the SOFAS predicts self-reported social adjustment and interpersonal problem scores. In the latter study, symptom distress (Global Severity Index of the Symptom Checklist-90-R) predicted both the GAF and the SOFAS, although distress was more strongly related to the GAF. Some have questioned the discriminant validity of the SOFAS, noting that a revised GAF that is nearly identical to the SOFAS correlated with symptoms as strongly as or stronger than a quality of life scale (Roy-Byrne, Dagadakis, Unutzer, & Ries, 1996). Although the overall evidence on SOFAS validity thus appears mixed, calls continue for Axis V to consist solely of adaptive functioning as a way of decoupling symptom distress and functional impairment (e.g., Gruenberg & Goldstein, 2003) or to split Axis V into several different areas of symptom distress and impairment (J. A. Kennedy & Foti, 2003).

Other unidimensional impairment scales, either derived from official *DSM* scales or developed independently, have been employed in clinical and epidemiological research. A version of the GAF specific to children and adolescents,

the Children's Global Assessment Scale (CGAS), has been published (Shaffer et al., 1983). The CGAS continues to base ratings on either symptoms or impairment but aims to provide anchor point descriptions that are more appropriate for children and adolescents. Bird et al. (1996) report positive validity evaluation for both a nonclinical version of the CGAS as well as the Columbia Impairment Scale (CIS), a 13-item Likert-format scale that uses items from several domains (interpersonal relations, broad psychopathological domains, functioning in work or school, and use of leisure time) but is scored unidimensionally.

Common multidimensional scales of functional impairment used in child clinical research include the Child and Adolescent Functional Assessment Scale (CAFAS), the Functional Impairment Scale for Children and Adolescents (FISCA), and the Social Adjustment Inventory for Children and Adolescents (SAICA). These are selected as representative measures, as many others exist and it is not the purpose of this discussion to provide an exhaustive review (see Canino et al., 1999, for more information on other scales). These scales often require specific information from the youth being rated as well as collaterals such as parents or teachers, in addition to including items more dependent of clinical judgment. The CAFAS consists of 165 behavioral descriptions selected by the rater that fall into five domains: role performance (including school/work, home, and community subscales), behavior toward others/self, moods/self-harm (including emotions and self-harmful behavior subscales), thinking, and substance use (Hodges & Wong, 1996). Commentators have noted that aside from those on the role performance scales, CAFAS items are closely related to psychiatric symptoms (Bird, 1999). Bates (2001) has questioned whether the validity database on the instrument is complete enough to support its widespread use in service eligibility contexts.

The FISCA is conceptually based on the CAFAS but is briefer (85 items) and is designed to have a somewhat streamlined response format. It has a hierarchical factor structure in which eight lower-order domains (aggression, thinking, home behavior, delinquency, alcohol and drugs, school behavior, self-harm, and feelings and moods) are grouped under three higher-order domains of undercontrolled aggression, social role violations, and self-focused impairment (S. J. Frank, Paul, Marks, & Van Egeren, 2000). Structural agreement has been noted between parent- and adolescent-report versions of the instrument (S. J. Frank, Van Egeren, Fortier, & Chase, 2000). The SAICA consists of 77 items designed to be administered in a semi-structured interview by clinicians. Items are grouped under four broad domains: school, peer relations, home life, and

spare-time activities (John, Davis, Prusoff, & Warner, 1987). Although the SAICA provides relatively rich item content and allows assessment of a variety of social roles in different contexts, it combines competence-related items with more symptomatic content (e.g., bullying, inattention) in the total score (Bird, 1999).

An additional strategy in the assessment of functional impairment is the use of symptom-specific judgments that are tied into the diagnostic interview itself, rather than separate axes, questionnaires, or interviews. The Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello, 1995, 2000) requires interviewers to revisit endorsed symptoms (whether or not formal diagnostic thresholds are met) and assess disability related to each area of psychopathology. Reporting on a factor analysis of such disability data, Ezpeleta, Keeler, Erkanli, Costello, and Angold (2001) show that the CAPA disability questions tend to group into three domains of family, peer, and school impairment. They also report several complex demographic and disorder type differences on manifestations of impairment. This research, taken along somewhat different lines than that of the impairment measures just reviewed, represents an interesting and informative epidemiological angle on the classification of psychiatric disability in children and adolescents. Ezpeleta et al. decry the relative lack of attention paid to the impairment side of mental disorders in youth and call for more systematic research on the nature and measurement of psychiatric disability.

Overall, these instruments and interviews include several domains that are commonly seen as areas of competence from a developmental tasks viewpoint; examples include academic success, avoiding trouble with the law, positive relationships with peers and romantic partners, and effective participation in the larger society. In addition, however, multidimensional impairment indices commonly include areas, such as emotional state and self-harm, conceptualized as outside certain definitions of competence. A salient omission from most, if not all, unidimensional and multidimensional impairment scales is the lack of an explicitly developmental framework. That is, though clinicians and other raters clearly take developmental considerations into account when completing these measures, there is little discussion of whether or how domains of impairment change across developmental time in importance, boundaries, or evaluative standards (Masten & Curtis, 2000).

Studies examining predictors to and from functional impairment measures have, not surprisingly, identified symptoms as one of the most consistent predictors; however, some recent work has also emphasized taking into account onset and duration of disturbance in regression models pre-

dicting impairment (Ezpeleta, Granero, de la Osa, & Guíllamón, 2000). Childhood impairment ratings themselves have been found to be good predictors of disorder effects later in adolescence (Costello, Angold, & Keeler, 1999). Impairment adds unique predictive power (above psychiatric symptoms) for course and outcome of disturbance (Canino et al., 1999; Costello et al., 1999; Pine et al., 2002), which surely adds motivation under the *DSM* system for including impairment criteria to definition sets of mental disorders. In fact, Angold, Costello, Farmer, Burns, and Erkanli (1999) advocated that individuals with symptomatic impairment, but who do not meet official diagnostic criteria, should nonetheless be treated as if suffering from a psychiatric disorder. Pickles et al. (2001), analyzing CAPA data from the Virginia Twin Study of Adolescent Development, found that the additional predictive power of impairment ratings for later symptoms and diagnosis varied by disorder class (adding prediction above current symptoms for Conduct and Oppositional Defiant Disorders but not for Major Depression).

Controversies in the Role of Competence in the Classification of Psychopathology

Several ongoing controversies in the assessment and measurement of functional impairment and in the inclusion of competence-related criteria in the *DSM* system parallel debates noted earlier with respect to the definition and assessment of competence itself. One issue concerns *who decides*; that is, What standard is used to designate impairment and how is impairment information used to inform service delivery? Important issues here include informant agreement and cultural and contextual considerations. Regarding informant agreement, evidence that parents and children (or adolescents) will provide similar pictures of impairment is mixed, as is research on symptoms (e.g., Achenbach, McConaughy, & Howell, 1987). Using the FISCA measure, S. J. Frank, Van Egeren, et al. (2000) demonstrated strong structural and relative agreement between parent and adolescent inpatient report; however, not surprisingly, parents and adolescents tended to disagree on impairment ratings that concerned more private/intrapersonal domains of functioning. Using a measure based on the CIS, Kramer et al. (2004) showed evidence for generally poor agreement between parent- and adolescent-reported impairment. They also found that clinicians tended to rate problems reported only by parents as more serious than those reported only by adolescents.

Cultural factors in diagnosis are, of course, broader than even the question of where and how to set diagnostic

boundaries. *DSM-IV-TR* (American Psychiatric Association, 2000) includes a glossary of so-called culture-bound syndromes that lists psychopathological conditions described as indigenous to particular cultures. In this respect, the manual recognizes in some fashion that distress and disorder presentation varies markedly across cultural boundaries. However, even this limited acknowledgment was reduced during the editorial process, and cultural variations in the manifestation of “core” *DSM* disorders are generally limited to a sentence or two in introductory text for each section that then preface the “universal” criteria sets. Alarcón et al. (2002) provide an extended discussion of several issues related to cultural variables and psychiatric diagnosis, including content of criteria sets, diagnostic thresholds, overall classification systems, and epidemiology.

A methodological issue in the impairment literature related to the Who decides? question is employing categories versus dimensions in the assessment of functioning. Although there appears to be a strong consensus that functional impairment measures should take a continuous/dimensional format, this ultimately requires setting cutoff points for entry into services. Bird (1999) comments on the varied methods that researchers have used for determining “caseness,” noting that in practice, this tends to remain the province of clinical judgment. In addition, conceptions of caseness and need for intervention depend to a large extent on financial and practical considerations on what level interventions take place and whether or not to intervene at all. Of course, researchers and clinicians in areas of physical medicine have long struggled with similar debates, and conditions such as hypertension are often cited as continuous-risk illnesses in which intervention/prevention cutoffs are set in part by consensus and change based both on new findings and the larger medical context.

In addition, similar to the “internal versus external criteria” of competence issue, debate outside of impairment measurement research has raised the question of whether suffering and/or distress alone, without associated external disability, justifies a mental disorder diagnosis. In many ways, distress can be thought of as a psychiatric analogue to fever or physical pain, in that it is a signal of an adaptational threat but is also a sign of one’s bodily response. Simply adding “clinical significance” to disorder criteria sets will not solve this controversy, due in part to problems with circularity of such a criterion (Wakefield & First, 2003). In addition, evidence that adding a clinical significance criterion reduces disorder rates differentially by category of disturbance (Romano, Tremblay, Vitaro, Zoccolillo, & Pagani, 2001) suggests that when one

takes away impairment, certain classes of distress (e.g., some anxiety symptoms) are virtually normative. Clinical significance as currently implemented in the *DSM* system is also problematic because it refers to distress *or* disability and thus adds another potential confound to the classification process (Lehman et al., 2002).

Similarly, debates continue over the potential inclusion or exclusion in *DSM* of subthreshold and “mild” disorders. On the one hand, there is considerable confusion over how to conceptualize these disorders, leading to difficulties in interpreting research results due to heterogeneity of conditions (Pincus, McQueen, & Elinson, 2003). However, Kessler et al. (2003) analyzed data from the National Comorbidity Survey and found evidence for a continuous and graded correlation between severity of illness and later outcomes, without a marked inflection point at the mild severity level; similarly, Pickles et al. (2001) have reported a continuous relationship in their adolescent sample between symptom counts and concurrent impairment without an inflection point at diagnostic thresholds. Kessler et al. recommend that service utilization decisions be made on the basis of cost-effectiveness, including the potential benefit of preventing future deterioration of functioning in subthreshold cases. This issue also exemplifies possible tensions between service organizations and researchers: The former may be concerned about lack of third-party reimbursement for “nondisorder” conditions, and the latter desire inclusion of those conditions to spark new studies and to investigate and evaluate preventive interventions.

Overall, it is clear that researchers in areas of competence and in psychopathology, though often following somewhat independent traditions, have wrestled with some of the same conceptual and methodological challenges. However, as already noted, there are some promising areas of research (such as the epidemiology of impairment) that aim, directly or indirectly, to bridge these traditions. The next section of this chapter examines these links more explicitly by discussing theoretical models and empirical evidence from the developmental and child clinical literature related to connections between competence and psychopathology.

MODELS AND PERTINENT EVIDENCE LINKING COMPETENCE AND PSYCHOPATHOLOGY

As already noted, competence and psychopathology have numerous connections in the theoretical, historical, and empirical literatures concerned with behavior. In this section, we examine the possible explanations for the ob-

served co-occurrence of behaviors described in terms of competence and psychopathology in the lives of individuals, utilizing illustrative evidence supporting these explanations. The first set of explanations focuses on methodological issues that could produce spurious linkages, and the second set focuses on substantive causal explanations.

Confounded Meanings and Measures

Before examining the causal explanations for links between competence and psychopathology, it is important to consider the more mundane possibility that these types of behavior are related because the terms reflect overlapping concepts or overlapping methods rather than true causal processes. These possibilities could produce spurious associations in research linking psychopathology and competence.

Overlapping Concepts

As evident in the preceding sections on the history and definitions of these complex concepts, psychopathology and competence sometimes refer to the same behavior or opposite ends of the same dimension of behavior, or the same behavior is used as a marker for both types of judgment (positive or negative) about the quality of adaptive functioning. Thus, for example, routinely breaking the rules or laws of society is viewed as a symptom of psychopathology (externalizing symptoms or a criterion for Conduct Disorder) as well as an indicator of poor performance in the competence domain of socialized conduct. Similarly, academic achievement (and failure) is considered to be an age-salient developmental task for school-age children, a criterion by which impairment is judged in diagnostic manuals for psychopathology, and is a common criterion for mental disorders related to learning.

The pervasive criterion of impairment for most *DSM*-defined mental disorders presents a challenge for interpreting research on the linkage of competence to psychopathology because the diagnosis of disorder is inherently confounded with the level of competence, often on the most salient developmental tasks, and yet the criteria for impairment are not well-specified, so the degree of the confounding is unclear. Moreover, the severity of impairment is related to referral, and therefore the samples in clinical studies may be unrepresentative and restricted in range on competence (e.g., Costello & Janiszewski, 1990). For anxiety disorders, for example, impairment is often viewed as crucial for distinguishing between normative fears and disorder: "A useful rule of thumb is to judge the child's ability to participate in ex-

pected, age-appropriate social and academic activities" (Klein, 1994, p. 354).

Overlapping Measures

Measures utilized to assess both of these aspects of behavior may also have overlapping content, related in many cases to overlapping concepts. In other words, the operational definitions of competence and symptoms may overlap. Measures of externalizing symptoms, such as the Child Behavior Checklist (Achenbach, 1991), contain items that overlap with measures of social competence, such as "Gets in many fights" (Externalizing broadband scale, Aggressive Behavior narrow-band scale) or "Would rather be alone than with others" and "Shy or timid" (Internalizing broadband scale, Withdrawn narrow-band scale) or "Not liked by other kids" (Social Problems narrow-band scale). The Revised Class Play measure (Masten, Morison, & Pellegrini, 1985), often used to assess peer social competence, includes the item "Gets into a lot of fights" on the Aggressive/Disruptive scale, "Would rather play alone than with others" and "Very shy" on the Sensitive/Isolated scale, and "A person everyone likes to be with" on the Popular/Leader scale. Harter's (1982, 1998) perceived (self-rated) and observed (rated by teacher or parent) competence rating scales have items with wording such as "Always doing things with a lot of people their age" versus "Usually do things by themselves" and "Not well-liked by other kids" versus "Liked by most other teenagers."

Impairment measures used in diagnosing psychopathology contain many items found on competence measures. For example, one of the questions from the 14-item Columbia Impairment Scale asks the rater to judge, for children or adolescents who are in school, "how much of a problem the target has with her/his school work." In addition, longer impairment measures such as the CAFAS and FISCA have several items relating to poor school work and the consequences thereof. Yet, Harter's perceived competence measure also includes "Does very well at one's classwork" versus "Doesn't do very well at one's classwork" as a competence item.

When similar confounded measurement tools are used to diagnose psychopathology and measure competence in a particular study, it is not surprising to find significant correlations among measures or to find that children who meet diagnostic criteria have worse social or academic competence scores. Thus, some of the links found in research on competence and psychopathology stem from measurement artifacts and conceptual overlap. However, even when great care is taken to distinguish concepts and measure these concepts independently with nonoverlapping content, links

continue to be found between competence and psychopathology, both within and across time. These findings offer strong support to causal theories about the connections between competence and psychopathology.

Causal Models

Causal models and related empirical findings fall into three broad categories: (1) Common causes or chains of causes contribute to problems in both aspects of adaptation (the linkage is therefore spurious); (2) the symptoms of psychopathology contribute to competence problems; or (3) competence problems contribute to the development or exacerbation of psychopathology. There are also more complex models that combine these effects within or across time. These include bidirectional (transactional), progressive and cascade models. Figure 19.1 provides abstract illustrations of these models in their simplest forms.

Common Cause Models
